Critical Care Pharmacotherapy
DEDICATION

To my son, Alex, my wife, Sue, and my mother, Donna, for their unwavering support.

B. Erstad
CONTENTS

Preface
Brian L. Erstad, Pharm.D., FCCP, BCPS

Foreword
Joseph F. Dasta, M.S., FCCP; Curtis N. Sessler, M.D., FCCP, FCCM; Ashlee Dauenhauer, Pharm.D.; and Ohoud A. Aljuhani, Pharm.D.

Letter from ACCP
Judith Jacobi, FCCP, MCCC, BCPS, BCCCP, ACCP President 2014–2015

SECTION 1: SUPPORTIVE CARE

Chapter 1: Acid-Base Disorders
Curtis E. Haas, Pharm.D.; David C. Kaufman, M.D.; and Brian L. Erstad, Pharm.D., FCCP, BCPS

Chapter 2: Fluid Therapy in the Critically Ill Patient
Brian L. Erstad, Pharm.D., FCCP, BCPS

Chapter 3: Electrolyte Disorders in the Critically Ill Population
Jeffrey J. Bruno, Pharm.D., BCPS, BCNSP; and Todd W. Canada, Pharm.D., FASHP, FTSHP, BCNSP

Chapter 4: Nutrition Support Therapy in Critically Ill Patients
Amber Verdell, Pharm.D., BCPS, BCNSP; and Carol J. Rollins, M.S., RD, Pharm.D., FASHP, FASPEN, BCNSP

Chapter 5: Glucose Management in the Critically Ill Population
Chapter 6: Analgesia
Asad E. Patanwala, Pharm.D.

Chapter 7: Agitation and Comfort in the Intensive Care Unit
David J. Gagnon, Pharm.D.; Nicole Kovacic, Pharm.D.; and Gilles L. Fraser, Pharm.D., MCCM

Chapter 8: Delirium in Critically Ill Adults
John W. Devlin, Pharm.D., FCCP, FCCM

Chapter 9: Neuromuscular Blocking Agents
M. Claire McManus, Pharm.D., BS(Pharm)

Chapter 10: Shock Syndromes
Ishaq Lat, Pharm.D., FCCP, FCCM, BCPS; and Sajni Patel, Pharm.D., BCPS

Section 2: Infectious Diseases

Chapter 11: Appropriate Use of Antimicrobials
Scott T. Micek, Pharm.D.; and Marin H. Kollef, M.D.

Chapter 12: Pharmacokinetic and Pharmacodynamic Considerations for Antimicrobial Use in Critically Ill Patients
Douglas N. Fish, Pharm.D., FCCP, FCCM, BCPS-AQ ID

Chapter 13: Laboratory Testing Considerations
Kali Martin, Pharm.D.; Shanna Cole, Pharm.D.; and Michael Klepser, Pharm.D.

Chapter 14: Antimicrobial Resistance in the Critical Care Environment
Andrew M. Roecker, Pharm.D.; and Steven J. Martin, Pharm.D.

**Chapter 15:** Severe Sepsis and Septic Shock  
Seth R. Bauer, Pharm.D., FCCM, BCPS; Simon W. Lam, Pharm.D., FCCM, BCPS; and Lance J. Oyen, Pharm.D., FCCM, FCCP, BCPS

**Chapter 16:** Invasive Fungal Infections  
Kathryn R. Matthias, Pharm.D., BCPS-AQ ID

**Chapter 17:** Invasive Viral Infections in the Intensive Care Unit  
P. Brandon Bookstaver, Pharm.D., FCCP, BCPS-AQ ID, AAHIVP; and Caroline B. Derrick, Pharm.D., BCPS

**Chapter 18:** Antimicrobial Prophylaxis  
Keith M. Olsen, Pharm.D., FCCP, FCCM; and Gregory Peitz, Pharm.D., BCPS

---

**SECTION 3: NEUROCITICAL CARE**

**Chapter 19:** Status Epilepticus and Acute Seizure Management  
Eljim P. Tesoro, Pharm.D., BCPS; Karen Berger, Pharm.D., BCPS; and Gretchen M. Brophy, Pharm.D., FCCP, FCCM, FNCS, BCPS

**Chapter 20:** Traumatic Brain Injury and Acute Spinal Cord Injury  
A. Shaun Rowe, Pharm.D., BCPS; and Bradley A. Boucher, Pharm.D., BCPS

**Chapter 21:** Acute Management of Stroke  
Martina Holder, Pharm.D., BCPS; and Stacy Voils, Pharm.D., M.Sc., BCPS

**Chapter 22:** Critical Care Management of Aneurysmal Subarachnoid Hemorrhage  
Denise H. Rhoney, Pharm.D., FCCP, FCCM, FNCS; Kathryn Morbitzer,
SECTION 4: HEMATOLOGY

Chapter 23: Prevention and Treatment of Venous Thromboembolism
William E. Dager, Pharm.D., FCCP, FCCM, FCSHP, FASHP, MCCM, BCPS; and A. Josh Roberts, Pharm.D., BCPS

Chapter 24: Hemostatic Agents for the Prevention and Management of Hemorrhage in the ICU
Robert MacLaren, Pharm.D., MPH, FCCP, FCCM; Bradley A. Boucher, Pharm.D.,FCCP, FCCM; and Laura Baumgartner, Pharm.D.

Chapter 25: Laboratory Testing with Anticoagulation
Tyree H. Kiser, Pharm.D., FCCP, FCCM, BCPS

SECTION 5: ACUTE KIDNEY INJURY

Chapter 26: Acute Kidney Injury—Prevention and Management
Curtis L. Smith, Pharm.D., BCPS; and Thomas C. Dowling, Pharm.D., Ph.D., FCCP, FCP

Chapter 27: Drug Dosing in Acute Kidney Injury and Extracorporeal Therapies
Melanie S. Joy, Pharm.D., Ph.D., FCCP, FASN; Michael L. Bentley, Pharm.D.; and Katja M. Gist, D.O., M.A., MSCS

SECTION 6: LIVER/GASTROINTESTINAL
Chapter 28: Management and Drug Dosing in Acute Liver Failure
Andrew C. Fritschle Hilliard, Pharm.D., BCPS, BCCCP; and David R. Foster, Pharm.D., FCCP

Chapter 29: Acute Gastrointestinal Bleeding: Prophylaxis and Treatment
Salmaan Kanji, Bsc. Pharm, Pharm.D.; and David Williamson, B. Pharm, M.Sc., Ph.D., BCPS

Section 7: Acute Pulmonary Disease

Chapter 30: Pulmonary Arterial Hypertension
Steven E. Pass, Pharm.D., FCCP, FCCM, FASHP, BCPS; and Joseph E. Mazur, Pharm.D., BCPS

Chapter 31: Critical Care Management of Asthma and Chronic Obstructive Pulmonary Disease
Amanda Zomp, Pharm.D., BCPS; Katherine Bidwell, Pharm.D., BCPS; and Stephanie Mallow Corbett, Pharm.D., FCCM

Section 8: Cardiovascular Critical Care

Chapter 32: Acute Decompensated Heart Failure
Jo E. Rodgers, Pharm.D., FCCP, BCPS-AQ Cardiology; and Brent N. Reed, Pharm.D., FAHA, BCPS-AQ Cardiology

Chapter 33: Management of Acute Coronary Syndrome
Zachary A. Stacy, Pharm.D., M.S., FCCP, BCPS; and Paul P. Dobesh, Pharm.D., FCCP, BCPS-AQ Cardiology

Chapter 34: Management of Cardiac Arrest
Toby C. Trujillo, Pharm.D., FCCP, FAHA, BCPS-AQ Cardiology
Chapter 35: Acute Management of Arrhythmias
James E. Tisdale, Pharm.D., FCCP, FAPhA, FAHA, BCPS

Chapter 36: Pharmacologic Challenges During Mechanical Circulatory Support in Adults
Amy L. Dzierba, Pharm.D., FCCM, BCPS; and Erik Abel, Pharm.D., BCPS

Section 9: Other Urgencies and Emergencies

Chapter 37: Hypertensive Crisis
Jeremy Flynn, Pharm.D., FCCP, FCCM; Melissa Nestor, Pharm.D., BCPS; and Komal Pandya, Pharm.D., BCPS

Chapter 38: Medication Withdrawal in the Intensive Care Unit
Colgan T. Sloan, Pharm.D., BCPS; Robert French, M.D., MPH; Nicholas B. Hurst, M.D., M.S.; Stephen R. Karpen, Pharm.D.; and Mazda Shirazi, M.D., Ph.D.

Chapter 39: Endocrine Disorders
Robert L. Talbert, Pharm.D.

Chapter 40: Oncologic Emergencies
Ali McBride, Pharm.D., M.S., BCPS, BCOP; Michelle Nadeau, Pharm.D., BCPS; and Cory M. Vela, Pharm.D.

Section 10: Miscellaneous

Chapter 41: Drug Dosing in Special Intensive Care Unit Populations
Jeffrey F. Barletta, Pharm.D., FCCM

Chapter 42: Management of the Critically Ill Burn Patient
The origin of critical care as a specialty is open to debate. Critically ill patients have received care in groups near battlefields ever since organized large-scale fighting first occurred. In hospital settings, isolated postoperative units dedicated to critically ill patients have been reported since the early 1900s. However, the widespread need for mechanical ventilation (commonly called respirators at the time) of patients with polio during the epidemics of the 1940s and 1950s led to a tipping point in the formation of critical care specialization. One of the first papers describing the care of patients with polio referred to care “by a team” of clinicians, although pharmacists were not among the health professionals listed.\(^1\) In addition to ventilators, other technologies that began to have more widespread use in critically ill patients by the 1950s included rudimentary dialysis machines, AC electrical defibrillators, and transvenous cardiac pacing equipment.\(^2\) More invasive respiratory and hemodynamic monitoring tools were also increasingly used in the early intensive care units (ICUs) of the 1950s and 1960s. These developments in the care of critically ill patients necessitated specialization by physicians in areas such as internal medicine, trauma, and anesthesiology. Other specialized personnel such as nurses, respiratory therapists, and eventually pharmacists (circa 1970s–1980s) were needed to complement the increasing number of critical care physicians in more modern critical care units. Today, a multidisciplinary or interdisciplinary patient care team that includes pharmacists has become the practice mantra and is now the norm in many ICU settings.

The term intensivist is now used to describe physicians with critical care specialty training following primary residency training in areas like
internal medicine, surgery, anesthesiology, emergency medicine, pediatrics, and obstetrics and gynecology. The first certification examination for critical care specialization by physicians was offered within internal medicine in 1987 by the American Board of Medical Specialties. Board certification for intensivists is now available from several specialty boards. For pharmacists, critical care has been recognized as a unique specialty by the Board of Pharmacy Specialties, with the first examination offered in the fall of 2015; widespread support for this certification within the profession of pharmacy is evidenced by the petition for specialty recognition that was jointly submitted by the American College of Clinical Pharmacy (ACCP), the American Pharmacists Association, and the American Society of Health-System Pharmacists.

In addition to specialty recognition, there are many other indicators of the growth and advancement of critical care pharmacy practice. The number of unit-based (i.e., clinical) critical care pharmacists increases in each new survey of critical care pharmacy practice. Similarly, the number of accredited PGY2 critical care residencies continues to increase. Fellowships in critical care have been developed, albeit in smaller numbers. Critical care pharmacists have their own recognized specialty groups in professional pharmacy organizations, such as the ACCP Critical Care Practice-Related Network (PRN). Position and opinion papers have been published that discuss the scope, level (i.e., fundamental, desirable, optimal), and justification of critical care pharmacy services and the credentialing of critical care pharmacists.\textsuperscript{3,4} But perhaps the best testimonial to the advancement and success of critical care pharmacists is their own substantial involvement in interprofessional critical care societies, organizations, and associations.

The four largest professional groups in the United States with critical care practitioner membership are the American Thoracic Society, the American College of Chest Physicians, the American Association of Critical-Care Nurses, and the Society of Critical Care Medicine (SCCM). Together, these groups formed a loose association known as the Critical Care Societies Collaborative (CCSC), which was established in 2009 to work on common core critical issues. Of the
organizations that constitute the CCSC, the first to recognize critical care pharmacists in a meaningful way was SCCM, established in 1970—as evidenced by its involvement in governance and committee work. Since 1998, critical care pharmacists have had a recognized section (Clinical Pharmacy and Pharmacology) within the administrative structure of SCCM. Furthermore, critical care pharmacists have widespread involvement in governance and other aspects of SCCM, as evidenced by the pharmacists who have served in numerous high-level positions (including president), the highly respected awards and honors bestowed on critical care pharmacist members (e.g., Fellow of the American College of Critical Care Medicine, Master Critical Care Medicine, Shubin-Weil Master Clinician/Teacher: Excellence in Bedside Teaching Award), the number of pharmacists involved in SCCM educational programming and guideline development efforts, and the long-standing practice models that have recognized pharmacists as integral members of the critical care team. Moreover, pharmacists continue to make inroads in other national critical care organizations that have traditionally been more physician-centric; for example, the Neurocritical Care Society recently placed a pharmacist in the governance line leading to the presidency.

The preceding overview of the evolution of critical care pharmacy practice serves as the backdrop for this first edition of Critical Care Pharmacotherapy. A cursory look at the authors of the chapters in this textbook reveals many of the pioneers and thought leaders in critical care pharmacy practice. Several of these authors were the first pharmacists to establish decentralized, unit-based critical care pharmacy services in their institutions. Many of the authors have held high-level positions in organizations with critical care membership, and most have active educational training and research programs. I am honored to be part of this collective effort.

The choice of chapters for this text was not an easy one, and I am indebted to many colleagues for their helpful suggestions. Chapters in general medical and pharmacy textbooks are often compiled on the basis of disease states or organ systems, but neither of these approaches was deemed appropriate for a critical care text focusing
on pharmacotherapy. A pharmacologic approach to the chapters based on drug class was excluded because it would not integrate the disease-medications decision-making process that is reflective of actual practice. Ultimately, a combination approach was decided on. Many of the chapters are listed under an organ system section, but most of the specific chapters in each section use a medication-focused approach. Another large section of chapters pertains to supportive care because this reflects so many of the medications that are used in critical care practice. Finally, several miscellaneous topics, some of which involve special ICU populations, did not fit neatly into either the organ system or supportive care sections but were deemed necessary to present a complete picture of critical care pharmacy practice.

Although this text is primarily aimed at a critical care pharmacist audience, we hope that it will provide valuable information for other pharmacists who must periodically care for critically ill patients, as well as for other health professionals who care for critically ill patients and desire a pharmacotherapy-focused resource. Ultimately, the intent of this text is to better educate pharmacists and other health professionals on issues pertaining to critical care pharmacotherapy so that they can provide optimal care for our patients in an efficient and cost-effective manner.

recommendations for training, credentialing, and documenting and justifying critical care pharmacy services. Pharmacotherapy 2011;31:135e-175e.

When I began to establish my clinical practice in 1979 in the medical intensive care unit (MICU) at The Ohio State University Hospital (now Wexner Medical Center), I knew of only two pharmacists in the United States who were critical care specialists. The first was David Angaran, M.S., at the University of Wisconsin trauma ICU. During my hospital pharmacy residency at Ohio State, we visited the University of Wisconsin in 1975 and toured the ICU, where I met David. He had been in that role since 1972. I was so impressed with his level of involvement in the care of the ICU patient that I recall saying to myself, “I want to be like him someday.” The second was Thomas Majerus, Pharm.D., who had been practicing in the trauma ICU since 1977 at the Maryland Institute of Emergency Medical Services. He was also very involved with direct patient care. Clearly, both of these pharmacists filled an unmet need in pharmacotherapy, and they were practicing at a high level of clinical involvement, even in today’s terms. They were the true pioneers of critical care pharmacy.

My initial practice area in 1977 was pulmonary medicine, and my clinical responsibility at the college of pharmacy was to develop a practice site at the hospital for pharmacy students (B.S. program) to gain clinical experience. Please note that I was employed full-time by the college of pharmacy, not the hospital pharmacy, although I had a good relationship with the pharmacy department because I was a graduate of their residency. I decided to change my practice site in 1979 from pulmonary medicine to the MICU because the pulmonary medicine division became administratively responsible for establishing an ICU team with a pulmonologist as the attending physician. It sounded like an interesting area for a pharmacist. It may be of interest to know that I had no idea that critical care pharmacy would develop...
into what it is today. I had not considered the future potential of critical care; I was primarily interested in developing a site for pharmacy students to fulfill their clinical rotation requirements. As the adage goes, “I’d rather be lucky than good.”

Even in 1979, Ohio State had a relatively well-established clinical pharmacy program whereby “floor pharmacists” were assigned to certain nursing units to evaluate the appropriateness of drug orders and to verify these orders before sending them to the central pharmacy for dispensing. As such, a floor pharmacist was assigned to the MICU; however, floor pharmacists usually did not attend daily ICU rounds because they had duties in other nursing units in the hospital. As such, I was the first pharmacist to consistently attend daily MICU rounds. I had not completed a formal training in the area of critical care pharmacy because no formal training programs yet existed; therefore, this practice setting posed many learning opportunities for me. I learned on my own by reading as much as I could and asking a lot of questions of the critical care nurses and physicians. During one visit to the health sciences library, I went to the stacks under the letter “C.” I found several textbooks on critical care and a journal called Critical Care Medicine. I leafed through its pages and realized that it was the official journal of the Society of Critical Care Medicine (SCCM). I recall thinking “Wow, they even have a specialty society.” A few days later, I called the society to inquire about membership. After I provided a brief explanation of my activities, a staff member said that it sounded like I was part of the critical care team and said, “Of course you can join … we’d love to have you as part of this society.” I was flattered.

It seemed to me that critical care would be a natural specialty for pharmacists. Patients are often hemodynamically unstable, they receive many drugs, and the data on therapies pertaining to the critically ill patient were scant to nonexistent. I hoped someday there would be many pharmacists specializing in critical care.

In 1981, I switched my practice to the surgical ICU (SICU). This unit was very different because there was no floor pharmacist. The pharmacy department sent drugs for the nurses to prepare (i.e., reconstitute vials and make an intravenous admixture) and administer. I heard rumors about this unit, which appeared in desperate need of a
I later discovered that the main interaction of the nurse with a pharmacist was for nurses to frequently call the pharmacy and say something like “my gentamicin was late.” This was a ripe area for the total scope of pharmacy services, both distributional and clinical.

I decided to introduce myself to the physician director, Dr. Tom Reilley, an anesthesiologist. After I told him who I was, I’ll never forget his words to me: “Where have you been … I’ve been looking for a clinical pharmacologist since arriving here several years ago.” He told me to meet him the next day at 9 a.m. in the SICU. Honestly, I was scared to death that someone would ask me a question that I could not answer. On rounds, one of the first patients we encountered was shaving his beard; of course, he did not have a razor. Apparently, this elderly man was hallucinating. A review of his medication list revealed that he was receiving intravenous cimetidine 300 mg every 6 hours, and his serum creatinine was about 3–4 mg/dL. I sheepishly pointed this out on rounds and suggested that his altered mental status could be from excess cimetidine. Dr. Reilley turned to me and asked me the dreaded question, “How do we fix this?” Although I was prepared to speculate and provide theories, it dawned on me that he wanted an action plan. I said to hold the dose for 24 hours and reinitiate cimetidine 300 mg every 12 hours. The order was changed according to my suggestion. A few days later, his mental status was better. Little did I know that, years later, I would be part of the SCCM clinical practice guideline on pain, agitation, and delirium!

The care of the critically ill patient in the early 1980s was much different from today. For example, most mechanically ventilated patients were heavily sedated. It was believed that ICU patients are best served if they don’t participate in their care and have no memory of their critical illness. There is an observation made by Dr. Tom Petty at the University of Colorado, in mid-1998, where he reflects on seeing patients in the ICU motionless, sedated, paralyzed, and appearing to be dead, except for the monitors that told him otherwise.² I suspect that if I had suggested early mobility, it would have sounded like heresy.
Many patients in the ICU, particularly the SICU, had pulmonary artery catheters. As such, several hemodynamic monitoring variables were generated, often many times per day. All of this information plus laboratory results, drugs, and so forth was on paper-based flow sheets. It was difficult to make sense of the volume of data. Regarding the paper medication administration record, at least at Ohio State, the scheduled drugs were on the front page, and the as-needed drugs were on the reverse side. As I recall, we often ignored the as-needed drugs like analgesics and sedatives because that was considered a “nursing issue.” Common orders included morphine 2–8 mg every 1–4 hours as needed, lorazepam 1–4 mg every 4–8 hours as needed, haloperidol 2.5–10 mg every 8–12 hours as needed, and diphenhydramine 25–50 mg intravenously every night at bedtime as needed for sleep. When I reviewed this page, I recall concluding that it appeared to be the nurse who was selecting the drug, the dose, how often to administer, and what parameter to monitor.

In addition to clinical practice and precepting B.S. pharmacy students, I initiated some clinical research studies. I quickly learned how difficult it was to conduct research in such an unstable population. After about 15 years of performing these functions, the pharmacy department opened an SICU/perioperative satellite pharmacy and later hired a Pharm.D. specifically for the SICU. My role changed to more of a clinical consultant, educator, and clinical researcher. My interaction with the SICU clinical pharmacist served as a model for optimal collaboration between hospital- and college-paid faculty. We co-precepted Pharm.D. students and collaborated on several clinical research studies.

During this time, I established one of the nation’s first residencies in critical care pharmacy. My first resident was a woman who had just completed her Pharm.D. degree. She was passionate about the care of the critically ill patient. I soon realized that she was a very talented person; beyond being smart, hard-working, and an excellent communicator, she was able to step back and examine the big picture in ways that I could not have imagined. Of course, I’m referring to Judi Jacobi, Pharm.D., who became the first pharmacist president of SCCM in 2010 and is the 2015 president of ACCP.
During my tenure at Ohio State, I was fortunate to train 11 residents and 9 fellows. My first fellow was Robert Weber, whose program was funded by an ASHP grant in 1980. Bob is now administrator of pharmacy services at Ohio State. I am very proud of all the accomplishments of my 20 residents and fellows.

There have been many changes in pharmacy and health care since I first established my clinical practice in the late 1970s. The pharmacy department has evolved from a revenue-generating center to a cost center after capitated reimbursement was initiated. This generated numerous initiatives focused on cost reduction of pharmaceuticals. In the area of professional organizations, the Critical Care Practice Research Network of the American College of Clinical Pharmacy (ACCP) is consistently one of the largest PRNs within ACCP. Regarding SCCM, the Clinical Pharmacy and Pharmacy (CPP) section was formed in 1989 and currently has more than 2,000 members. It is a very active section, with pharmacists serving on key committees of the section and within the SCCM organization. Furthermore, there is a designed CPP seat on the council. There are usually four or five pharmacists on the editorial board of Critical Care Medicine, many pharmacists have been members of clinical practice guidelines and a few have been chair, and a pharmacist was recently selected as program cochair for the annual congress. In 2015, the Board of Pharmacy Specialties (BPS) recognized critical care pharmacy as the seventh BPS specialty.

There usually are 70–80 critical care residencies, and many ICUs have pharmacist preceptors actively involved with direct patient care. However, the number of fellowships has dropped dramatically. It is of concern that so few critical care pharmacists are being trained for research-oriented academic positions. In addition, some critical care pharmacists are being diverted to other areas of the hospital, or they are being redirected to reduce drug costs. These changes are occurring despite data showing the important role of the critical care pharmacist. Clearly, the critical care pharmacist should focus on providing cost-effective, quality care.

In summary, critical care pharmacy is a well-established specialty in
the field of clinical pharmacy, which now has a board certification process. Thousands of ICU patients have benefited from critical care pharmacists providing excellence in patient care, leadership roles in professional societies, and clinical research resulting in improved outcomes. The future is bright. However, it will be important for pharmacists to be paid for their services and for organizations like the Joint Commission, Leapfrog, and the Centers for Medicare & Medicaid Services to endorse the critical care pharmacist as a crucial element in the provision of optimum care to the critically ill patient.

Curtis N. Sessler, M.D., FCCP, FCCM
I recently celebrated my 30-year anniversary as an attending physician in the intensive care unit (ICU) setting and was thrilled when Brian Erstad invited me to reflect on the journey of critical care pharmacotherapy. I have long been an enthusiastic believer that by getting the right people with the right skills in the right seats on the bus, one can be confident of achieving the best possible outcomes. This is certainly true in critical care medicine, where the sickest patients have the most complex management, often proceeding at the fastest pace.

Although I am confident that we have been providing the best care possible for many years, I personally count the addition of the clinical
pharmacist as a regular member of the ICU team as a sentinel moment in the quest to deliver high-quality patient care. I have had the very good fortune of working with some spectacular clinical pharmacists in a wide variety of settings—a reflection of the many roles that clinical pharmacists play and the different hats I’ve worn over the years. These roles have evolved to the point that, unquestionably, clinical pharmacists are essential for the optimal care of the individual ICU patient, as well as the safe, effective, and cost-conscious critical care delivered throughout hospitals around the world.

As is true for many clinicians, my most consistent appreciation for the clinical pharmacist is of the value added on a daily basis in their direct patient-centric role. The instances in which one of our clinical pharmacists has identified and corrected a potentially life-threatening drug interaction or adverse drug effect are too numerous to count. I recall one patient who had suffered a small stroke at another hospital but arrived to our ICU manifesting severe neurocognitive deficits. Our clinical pharmacist noted that the patient had been receiving an amiodarone infusion and recommended discontinuation as a potential cause of neurotoxicity. This patient rapidly improved and was eventually discharged home with good functional abilities.

Important roles our clinical pharmacists play in the daily management of ICU patients include participating in pharmacotherapy decision-making, providing pharmacokinetic consultation, identifying and mitigating potential drug interactions, taking steps to avoid or quickly recognize adverse drug effects, monitoring drug dosing and administration, and avoiding administration of costly or unnecessary medications. Widespread organ dysfunction, extensive lists of medications, and rapidly changing medical illnesses contribute to a fertile setting for the emergence of medication misadventure. In fact, among all patient groups, critically ill patients present perhaps the greatest challenges and therefore the greatest needs for the skills of a good clinical pharmacist. Although many ICU patients benefit from direct clinical pharmacist involvement, I consider the clinical pharmacist-physician partnership to be among the most powerful patient-care tools in the intensivist’s armamentarium. In fact, one might consider this partnership to reflect the collective expertise as the therapeutic
strategists who design and implement the pharmacologic therapeutic plan, as well as therapeutic tacticians who make fine adjustments to medications in the heat of medical battle. Together with ICU nurses, clinical pharmacists and physicians establish the core of the ICU team that provides patient-centered care.

My experiences as medical director for our medical ICU, as well as other leadership roles in the critical care community throughout our institution, have broadened my appreciation for the many important contributions by, and the unique expertise of, clinical pharmacists with respect to tackling important system-wide issues. Our clinical pharmacists are at the forefront of a wide variety of educational, administrative, and local policy-making activities. Many important activities focus on traditional pharmacy-based issues, but typically with an eye to educating and assisting other members of the health care team. For example, like many hospitals, we have experienced shortages of critical medications including vasopressors, sedative and opioid medications, and others. Our clinical pharmacists’ action plans have included detailed and evidence-based guidelines for substitution medications with matching educational programs for all affected clinicians. In addition, our clinical pharmacists routinely serve as key members of multiprofessional taskforces that create order sets, checklists, treatment algorithms, and other tools and documents.

As an academician, I am delighted that we have a strong culture of scientific inquiry in our critical care community. Our clinical pharmacists are highly engaged and often lead the way in the process of addressing clinically relevant questions through clinical research and scholarly analysis. I’m proud of our clinical pharmacists who routinely present posters at national meetings and publish important original investigations and reviews. One of the more noteworthy accomplishments from the ICUs at our institution—developing and validating the Richmond Agitation-Sedation Scale (RASS)—initially emerged from a bedside conversation several clinical pharmacists and I were having about adjusting sedative medications. We concluded, let’s make a better patient assessment tool and build one that includes the viewpoints of all the key stakeholders—nurses, pharmacists, and physicians—for this important and common problem.
For the past decade or so, I have had increasingly frequent collaboration with clinical pharmacy colleagues on several national projects, including serving on work groups addressing critical care workforce shortages, clinical practice guideline writing committees, and expert panels to address important problems like managing pain in the ICU. It is clear that clinical pharmacy is a discipline at the heart of critical care practice, research, and education and that clinical pharmacists provide the unique expertise that complements that of nurses, physicians, and other individuals, all striving to provide superlative patient care.

I conclude by applauding Dr. Erstad for leading a distinguished group of contributors in creating an outstanding textbook of critical care pharmacotherapy. I am grateful for the opportunity to contribute and, in doing so, to help celebrate the tremendous work performed by my clinical pharmacy colleagues.

Ashlee Dauenhauer, Pharm.D.

As a new practitioner in the field of critical care, I was ready to take my 8+ years of higher education and make a difference in patients’ lives. What I quickly found is that the reality of daily patient care is much more complex than what is taught during those fruitful years of training. Even after a rigorous 2-year residency program, where I was seemingly exposed and prepared for every situation, I realized how much untapped knowledge exists in medicine. Nevertheless, some of the most indispensable information I have gained in the field of health care resulted from my daily experiences in the intensive care unit (ICU). As I reflect on my years of training and the first year of my career as an ICU pharmacist, I am exceptionally pleased with my decision to pursue the area of critical care.

I was first exposed to the acute care setting as a fourth-year pharmacy student during clinical rotations. At that time, I had a limited preconceived notion of what clinical pharmacists actually did on a daily basis. However, after observing my preceptors, I acknowledged the potential impact that pharmacists have on patient care through diligent
patient and physician interaction. When I began my pharmacy residency, I was fortunate enough to train in a program that already had well-established clinical pharmacist positions. Pharmacists and pharmacy residents at the University of Arizona Medical Center have a recognized and respected relationship with other members of the health care profession. Training at an institution with a valued pharmacy presence has allowed me to grow exponentially in medical knowledge, workload efficiency, and team communication.

As a clinical pharmacy resident, I was much more involved with direct patient care than I had originally perceived. I was available at the patient’s bedside to provide real-time medication-related recommendations and assistance for complex treatment plans. This decentralized pharmacy model allowed me to resolve medication-related issues immediately, creating more time for other health care professions such as physicians and nurses to provide excellent patient care. This pharmacist-physician collaboration also provided the patient with a multidisciplinary crafted treatment plan, consisting of the most evidence-based, cost-effective, and accessible medications. Although there has been substantial growth in clinical pharmacist positions among institutions, many are still without this multidisciplinary model. A focus of expanding this position to include a pharmacist on every unit is a current objective at my own institution, which will hopefully continue to improve health care collaboration and optimize patient care.

After accepting a position as a critical care pharmacist, I was placed mainly in the cardiothoracic ICU. Experiencing this specific unit made me recognize the importance of having specialty-trained pharmacists in all capacities of health care. Much like other areas of medicine, having the wealth of knowledge and experience with every single medication and interacting disease state is difficult because of the dynamic parameters that change with different patient populations. Being proficiently trained in medication pharmacodynamics, pharmacokinetics, and pharmacoeconomics specifically in the cardiothoracic population has given me comprehensive knowledge for the medications and disease states observed in this specialty area. This foundation includes acute decompensated heart failure requiring mechanical circulatory support and valve replacements as well as
initiation, regulation, and monitoring of anticoagulation for cardiac
device patients such as left ventricular assist devices, total artificial
hearts, and extracorporeal membrane oxygenation.

After completing the first full year of my career, I find that being a
new clinician has made me realize how far health care still needs to
progress in the future. The proverb that “medicine is not black and
white” could not be truer in the critical care setting. Many health care
professionals practicing in this area can verify that the textbook
patients included in medical studies simply do not exist in the ICU
because of a perpetually aging population surrounded by many
comorbidities. Therefore, providing optimal patient care established by
evidence-based medicine becomes increasingly challenging in many
cases. I believe that continuing to observe modern medical practice
outcomes through research in every patient population will undoubtedly
benefit the progression of health care. This past year, I have begun to
direct my focus in clinical studies occurring at my institution, specifically
in the cardiothoracic ICU setting. I hope to continue participating in
research to further advance medical practice in cardiothoracic devices,
all while providing my services to both patients and other health care
professionals to make a difference in patients’ lives.

Ohoud A. Aljuhani, Pharm.D.
Where I stand today is at the culmination of a journey that began 5
years ago when I took the first steps toward becoming a specialist in
critical care pharmacy. As a pharmacist with a stable career at one of
the largest universities and academic medical centers in Saudi Arabia, I
found the decision to go back to school, travel to the United States,
and start all over again to be a difficult one. I look back on my journey
with no regrets.

In 2007, I began practicing as a clinical pharmacist in the medical
intensive care unit (ICU) at King Abdul-Aziz University (KAU) Medical
Center in Jeddah, Saudi Arabia. I remember my first day on the job
seeing how excited the medical ICU team was to have a clinical
pharmacist working with them. Even though the pharmacy profession
had been well established in my country for more than 50 years, clinical pharmacy practice was still in its infancy. Although some specialty health care centers were practicing clinical pharmacy, most government-run hospitals, including KAU Medical Center, had yet to establish services, despite a growing patient population. A major step toward initiating these services was establishing the first Pharm.D.-granting institution in the country at KAU. Among the first group of graduates from this school, I was honored to participate in such a new and unique program.

After graduation, with the passion and energy of a young practitioner, I accepted a shared position with the School of Pharmacy and KAU Medical Center. This position provided mentors and guidance that helped me throughout my career. Initiating clinical pharmacy services in the ICU of a hospital with 500 beds was certainly a challenge. To meet this challenge, I sought advice from experienced clinical pharmacists, actively participated in the implementation of ICU pharmacotherapy protocols, participated in several hospital committees, made rounds with medical ICU teams, provided daily recommendations about therapies, and assisted with the training of pharmacy students at the hospital.

While practicing clinical pharmacy in the ICU's trauma/surgical and medical departments, I became aware of the need for well-trained clinical pharmacists in these areas. This moment of realization was the principal force driving me to make one of the important decisions in my life—to seek professional training in critical care pharmacotherapy. Unfortunately, the only available residency program in Saudi Arabia at that time was for general pharmacy training. Therefore, I made the decision to travel to the United States and receive specialized training in critical care pharmacotherapy at one of the country's top academic medical centers.

What I have learned and practiced in this program during the past few years has lit a candle of hope that I will carry back to my country. My postgraduate education has helped me become a well-trained and capable critical care pharmacist and researcher and will allow me to actively participate in the development of clinical pharmacy services in Saudi Arabia. If you are reading this book and hoping to play an active
role in improving clinical pharmacy practice in your country, this foreword is dedicated for you.
LETTER FROM ACCP

Judith Jacobi, FCCP, MCCM, BCPS, BCCCP, ACCP
President 2014–2015

When I consider the literature of critical care pharmacotherapy, I recall with fondness the text edited by Bart Chernow, M.D., FCCM, Master FCCP, initially published in 1983, titled The Pharmacologic Approach to the Critically Ill Patient. However, it was the third edition that embraced the role of the critical care team and included a large number of pharmacist authors.¹ This version blended pharmacology with the clinical nuance of critical care therapeutics. This “antique” remains in my library as an important reminder of both a simpler time and the tremendous progress we have made—and still how much we need to learn to optimally care for these patients. For those of us with long careers in critical care, books like this lend an important perspective on current practices and their foundation.

Much time has passed, and many other publications have come and gone from my critical care library. Critical care journals and other periodicals are generating data at a dizzying rate. One might ask how another textbook could contribute to the training and effectiveness of critical care clinicians. However, that is easy to answer with a publication of the quality of Critical Care Pharmacotherapy, which compiles key information in a format that illustrates our current understanding of pertinent therapeutic and pharmacologic topics. Indeed, this book will establish a new basis for future research and knowledge development and will hopefully become a foundational text for new practitioners and the growing number of Board Certified Critical Care Pharmacists.

Brian Erstad has assembled an impressive group of authors, many of whom are friends and colleagues in critical care pharmacy and have done the cutting-edge research that contributes to this expansive
work. Many other talented and dedicated clinicians and researchers will be cited, but most contributors will remain in relative obscurity as our specialty continues to mature. As a past president of ACCP, I want to thank the efforts of the growing number of critical care clinicians who make such a difference in the care of our patients and who have contributed to the Critical Care Practice and Research Network and to this text. I anticipate that we will all use this text for our own education and as a teaching tool for future generations.

Section 1

Supportive Care
LEARNING OBJECTIVES

1. Explain the common contributors to and potential clinical consequences of acid-base disorders in the critically ill patient.

2. Appreciate the differences between the traditional physiologic (carbonic acid-bicarbonate), standard base excess, and physiochemical (Stewart) models of acid-base physiology.

3. Complete the stepwise approach to assessment and reach a correct conclusion concerning the acid-base status of a critically ill patient.

4. Define the independent and dependent variables in acid-base physiology and their relevance to understanding the mechanisms and treatments for common acid-base disturbances.

5. Summarize the common causes, presentations, complications, and treatments for acid-base disorders commonly observed in critically ill patients.

6. Explain the relationship between fluid and electrolyte therapy and acid-base disturbances in critically ill patients, and explain how choice of fluids used during resuscitation can influence acid-base balance.

**INTRODUCTION**

Acid-base disorders are common findings in critically ill patients, are often complicated and multifactorial in nature, and are associated with significant morbidity and mortality. The diagnosis of the underlying causes of an acid-base disorder in critically ill patients is further complicated by concomitant and dynamic abnormalities in plasma protein concentrations, electrolyte profiles, free water or overall extracellular volume status, and ventilatory status. Given the often-
complicated nature of the presentation, a simplistic or casual approach to evaluating acid-base disorders is inadequate for the intensive care unit (ICU) environment and may lead to a missed diagnosis or a complication that needs treatment. Although the mainstay for managing an acid-base disorder remains treatment of the underlying processes, a full understanding of the contributors to the acid-base status may identify a need for specific therapeutic interventions. This chapter is focused on an understandable and practical, but comprehensive, approach to assessing and managing the acid-base disorders commonly encountered in critically ill patients.

Several studies that have evaluated diagnostic approaches to metabolic acidosis provide some insights into the frequency of this disorder in different ICU settings. Cusack and coworkers reported on 100 consecutive adult patients admitted to a mixed medical-surgical ICU. Standard base excess (SBE) was abnormal in 57% of patients, corrected base excess (BE) was decreased in 86%, and corrected anion gap (AG) was elevated in 100%, indicating that laboratory evidence of metabolic acidosis was very common. Of 427 patients admitted to an adult trauma ICU, hyperlactatemia was present in 18%, hyper-chloremia in 21%, and an elevated strong ion gap (SIG) in 92%, consistent with evidence of metabolic acidosis. Dubin et al. reported results from 935 patients admitted to a mixed medical-surgical ICU. The SIG and corrected AG were elevated in 71% and 74% of patients, respectively, and hyperlactatemia was evident in 34%, with 6% of patients having a lactate concentration greater than 5 mEq/L. Chawla et al. reported on 143 patients admitted to a medical-surgical ICU. The mean albumin-corrected AG was 14.1 plus or minus 3.8 mEq/L, and 16.3% of patients had hyperlactatemia, despite the exclusion of patients with ketoacidosis, serum creatinine (SCr) greater than 6 mg/dL, or a history consistent with toxic ingestions. Although most series have reported on evidence of metabolic acidosis, Liborio and coworkers evaluated serum bicarbonate concentrations from a database of 18,982 ICU patients for evidence of metabolic alkalosis, excluding patients with evidence of pure respiratory acidosis. During their ICU stay, 5,655 patients (29.3%) had a serum bicarbonate
concentration greater than 30 mEq/L for at least 1 day, with most patients (86.6%) experiencing metabolic alkalosis within 72 hours of admission to the ICU. In addition, 17.9% of patients included in this database had evidence of a persistent metabolic acidosis. Most patients with an elevated serum bicarbonate concentration also had a metabolic acidosis at some point in their ICU stay. Only 11.4% had serum bicarbonate concentrations in the reference range throughout their ICU admission. Although several of these reports may overestimate the overall prevalence of acid-base disorders in critically ill patients, because of the inclusion of only patients who underwent arterial blood gas (ABG) measurements, it is abundantly clear that metabolic acid-base abnormalities are common in the ICU. When the picture also includes all ICU patients with predominantly respiratory acid-base disorders, the argument is further strengthened that acid-base abnormalities are one of the most ubiquitous and heterogeneous disorders requiring assessment, monitoring, and treatment in critically ill patients.

The many potential contributing factors to acid-base abnormalities in critically ill patients will be discussed in much greater detail later. The major organ systems responsible for regulation of acid-base homeostasis are the respiratory and renal systems, with a lesser contribution from the liver. Therefore, dysfunction or failure of any of these systems, not uncommon in the critically ill patient, is expected to be associated with acid-base disorders. Although the gastrointestinal (GI) system does not regulate acid-base balance, dysfunction or diseases of the GI tract including vomiting, high nasogastric tube output, diarrhea, ileostomy losses, villous adenoma of the colon, and high-volume pancreatic/biliary fluid drainage can contribute to metabolic acid-base imbalances. Sepsis, shock, hypoxemia, trauma, microvascular dysfunction, dysregulation of cellular metabolism, hypoalbuminemia, renal replacement therapy, and many electrolyte disorders can also contribute to metabolic acid-base abnormalities. A variety of toxic ingestions may be associated with metabolic acidosis (e.g., alcohols, glycols, salicylates, iron). Iatrogenic factors in the ICU that can contribute to abnormal acid-base status include fluid
resuscitation with high-chloride fluids (e.g., 0.9% sodium chloride solution), drugs (e.g., propofol, lorazepam, CNS depressants), over- or under-ventilation during mechanical ventilation, and total parenteral nutrition.\textsuperscript{6,8,9} It is important to appreciate that acid-base disorders are not only a result of the underlying illness leading to ICU admission, but can also adversely be affected by the management of those illnesses and general supportive care.\textsuperscript{10}

Although disorders of acid-base balance have been associated with increased ICU length of stay and increased mortality,\textsuperscript{2,5,11,12} the findings are not universal.\textsuperscript{1,13} The direct impact or attributable morbidity or mortality from metabolic acid-base disorders is controversial and difficult to separate from the contributions of the underlying illness.\textsuperscript{8} Persistent severe acidemia (pH less than 7) or alkalemia (pH greater than 7.6) is considered incompatible with life; however, the cause-and-effect relationship with poor outcomes for more transient and moderate derangements of acid-base status is not conclusively shown.

Elevated blood lactate concentrations, regardless of the cause, have been associated with increased mortality, especially with sustained elevations or very high concentrations of lactate.\textsuperscript{14} In a randomized, multicenter trial, early lactate-directed resuscitation led to a significant decline in risk-adjusted mortality (hazard ratio 0.61; 95% confidence interval, 0.43–0.87).\textsuperscript{15} There is also growing evidence that using chloride-rich crystalloid therapy compared with a more balanced fluid after major surgery or after an ICU admission is associated with a greater frequency of acute kidney injury, more need for renal replacement therapy,\textsuperscript{16,17} and higher in-hospital mortality.\textsuperscript{16} Although these lines of evidence do not validate that treatment of acid-base disorders improves outcome independently of treating the underlying disease state, they do suggest that therapeutic approaches to the underlying problem that either improve or do not induce or exacerbate preexisting acid-base abnormalities are associated with better outcomes.

\textbf{TERMINOLOGY AND CONCEPTS}
In discussing acid-base analysis and the common abnormalities of acid-base status, the following terms and concepts are important to understand.

**Acid and Base**

For this chapter, we will use the definitions of an acid and base offered by Stewart. An acid is a substance that increases the oxonium (formerly called hydronium ion) concentration ([H$_3$O$^+$]) of a solution, and a base is a substance that decreases the [H$_3$O$^+$] of a solution. A decrease in [H$_3$O$^+$] is equivalent to an increase in [OH$^-$]. Water is amphoteric and can therefore act as an acid or base. Remember that a solution is neutral when the [H$_3$O$^+$] is equal to the hydroxyl ion concentration ([OH$^-$]).

**Analysis of -emia vs. -osis**

The usually accepted normal range for blood pH is 7.35–7.45, and throughout this chapter, we will use 7.4 as normal in all analyses. A blood pH of less than 7.35 represents an acidemia, whereas a blood pH of greater than 7.45 is an alkalemia. The terms acidosis and alkalosis define the underlying processes that lead to an acid-base disorder, but they should not be used to describe an abnormal blood pH value. For example, a patient may have a metabolic alkalosis and a respiratory acidosis or a metabolic acidosis and a respiratory alkalosis but a blood pH of 7.35–7.45.

**Analysis of pH vs. [H$_3$O$^+$]**

The pH value was adopted more than 100 years ago to express blood [H$_3$O$^+$] in clinical medicine. The pH is the inverse log$_{10}$ [H$_3$O$^+$] and is therefore an unfortunate, dimensionless, non-linear, and non-intuitive expression of the [H$_3$O$^+$]. Because of its nonlinear nature, a greater change in [H$_3$O$^+$] is needed to decrease the pH to the acidemic range than the change in [H$_3$O$^+$] resulting in an alkalemia. Although it is
possible to manage acid-base disorders while working with the $[\text{H}_3\text{O}^+]$ in the physiologically and pathologically relevant pH range of 6.8–7.6 ($[\text{H}_3\text{O}^+]$ range of 160 nmol/L to 25 nmol/L, respectively), it is highly unlikely that $[\text{H}_3\text{O}^+]$ will supplant the use of pH in clinical medicine in the near future.

### Strong vs. Weak Ions

Strong ions are essentially fully dissociated in solution; therefore, there is no dissociation equilibrium applicable to these electrolytes (e.g., Na$^+$ and Cl$^-$). Because they are fully dissociated at all times, they do not participate in any reactions within the solution. Weak ions, which are by definition only partly dissociated in solution, are defined by the following equilibrium expression:

$$[H^+] \times [A^-] = K_A \times [HA]$$

where HA is a weak acid, H$^+$ and A$^-$ are the dissociated proton and anion, and $K_A$ is the weak acid dissociation constant.

### Electroneutrality

In any aqueous solution, the sum of all positively charged and all negatively charged ions must be equal, resulting in an electrically neutral solution. It requires excess energy to maintain a charged solution, so an electrically neutral solution is naturally energetically favored. In vivo, any macroscopic fluid volume (e.g., plasma, extracellular fluid) will be electrically neutral, creating a link between the nonreactive strong ions and the equilibrating weak ions.

### Conservation of Mass

The amount of substance in solution will change only if it is added, removed, generated, or destroyed. The relevance relative to clinical acid-base status is that strong ions like Na$^+$ and Cl$^-$ only change
quantitatively if they are added or removed, whereas organic acids like lactate and pyruvate can be generated or metabolized. For partly dissociated substances, the total concentration is the sum of the dissociated and undissociated forms, which will equilibrate depending on the presence of other constituents in the solution.

**Anion Gap**

The AG is widely used in the diagnostic workup of metabolic acidosis. It represents the difference between the concentration of commonly measured and most abundant serum cations (Na\(^+\) and K\(^+\)) and anions (Cl\(^-\) and HCO\(_3^-\)). The equation for the AG is as follows:

\[
AG = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) \tag{1}
\]

where the concentration of each electrolyte is expressed as milliequivalents per liter. Because of the greater concentration of total unmeasured anions compared with unmeasured cations in equation 1, the normal range for the AG is usually quoted as 12 plus or minus 4 mEq/L. The actual value depends on the normal ranges for the reporting laboratory, which will vary depending on analytic methodology.\(^9,20,21\) Because of the relatively narrow and tightly controlled range of serum [K\(^+\)], the equation is often simplified in clinical practice:

\[
AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \tag{2}
\]

For this simplified equation, the normal range is 8 plus or minus 6 mEq/L. However, in the critically ill population, there is often greater variability in serum [K\(^+\)], and some authorities recommend not ignoring potassium’s contribution to the AG.\(^9,22\)

The major contributor (about 80%) to the serum AG is albumin, which is consistently low in critically ill patients. Hypoalbuminemia results in a falsely low serum AG and poor diagnostic performance; therefore, the AG must be corrected for the albumin concentration for all critically ill patients. For every 1-g/dL change in serum albumin, there is a directional change in the AG by 2.3–2.5 mEq/L.\(^21,22\) A widely used
equation for calculating the albumin-corrected AG (ACAG) is as follows:

\[
ACAG = AG + 2.5([\text{normal albumin}] - [\text{observed albumin}])
\]

The albumin concentrations are in grams per deciliter, and the normal albumin concentration should be the local laboratory normal value.

**ACID-BASE MODELS: ANALYSIS AND INTERPRETATION**

**Traditional, Physiologic, or Bicarbonate-Centered Model**

This model is based on the work of Henderson and Hasselbalch from more than 100 years ago and remains the most commonly used model for describing and interpreting acid-base disturbances.\(^{23-25}\) This model is based on the assumption that the carbonic acid-bicarbonate buffer system is the major determinant of acid-base balance and is described by the Henderson-Hasselbalch equation:

\[
\text{pH} = \text{pK} + \log_{10} \left( \frac{[\text{HCO}_3^-]}{0.03 \times \text{Paco}_2} \right)
\]

where pK is the dissociation constant for carbonic acid (6.1), Paco\(_2\) is the arterial blood partial pressure of carbon dioxide (CO\(_2\)) in millimeters of mercury, [HCO\(_3^-\)] is the plasma bicarbonate concentration (measured as total CO\(_2\) content) expressed as milliequivalents per liter, and 0.03 represents the solubility of CO\(_2\) in plasma. From this model followed the concept that the major determinants of [H\(_3\)O\(^+\)] are changes in Paco\(_2\) and [HCO\(_3^-\)] and that these parameters are adjusted in vivo as a control system to regulate alterations in acid-base balance. Disorders that are predominantly associated with alterations in Paco\(_2\) are respiratory disorders, whereas those that are primarily associated with alterations in [HCO\(_3^-\)] are metabolic disorders. This model is based on the equation describing CO\(_2\)/HCO\(_3^-\) equilibrium with carbonic
assuming that this reaction will equilibrate (Le Châtelier’s principle),
metabolic acidosis has therefore been explained by either the addition
of $\text{H}^+$ to the system, shifting the reaction to the left with a reduction in
$[\text{HCO}_3^-]$, or the loss of bicarbonate from the body, shifting the reaction
to the right to replace lost bicarbonate and increasing $[\text{H}^+]$.\textsuperscript{25} It has
also been taught that metabolic alkalosis is attributable to factors that
can either increase the $[\text{HCO}_3^-]$ (e.g., bicarbonate generation and
reabsorption by the kidney or contraction of the extracellular volume),
which will shift the reaction to the left with a decrease in the $[\text{H}^+]$, or
cause the loss of $\text{H}^+$ (e.g., vomiting), which will shift the reaction to the
right, leading to an increase in $[\text{HCO}_3^-]$.

Carbon dioxide is the primary volatile acid produced through normal
cellular metabolism, accounting for around 15,000 mmol/day of
hydrogen ion equivalents for an average adult. The $\text{CO}_2$ is expired by
the lungs. Sensitive receptors in the medulla and carotid and aortic
bodies respond to alterations in $[\text{CO}_2]$ in the cerebrospinal fluid and the
$\text{Paco}_2$ and $[\text{H}_3\text{O}^+]$ in plasma, respectively, leading to changes in minute
ventilation to maintain $\text{Paco}_2$ and pH within tight ranges. Changes in
ventilation to regulate acid-base disturbances are relatively rapid, with
a new equilibrium achieved in minutes to hours, meaning that changes
in minute ventilation and $\text{Paco}_2$ can rapidly compensate for a metabolic
acid-base disorder. In contrast, with a persistent abnormality in
ventilation leading to a chronic respiratory acid-base disorder, a
metabolic compensation develops slowly over 2–5 days.\textsuperscript{23,24}

Organic and inorganic non-volatile acids are produced to a lesser
extent than the volatile acid $\text{CO}_2$. Organic acids are predominantly
lactate and ketones, with about 1500 mmol/day being metabolized by
the liver and kidney. The two most important inorganic acids are sulfate
and phosphate, generated from dietary protein and amino acid
metabolism and contributing about 1.5 mmol/kg/day. Most lactate
undergoes hepatic metabolism either by an oxidative pathway to
generate water and CO$_2$ (and subsequently HCO$_3^-$) or by gluconeogenesis to glucose, with both pathways consuming protons and therefore contributing to the maintenance of acid-base balance. The traditional teaching is that the free protons (H$^+$) from organic and inorganic acids are rapidly buffered by the bicarbonate-carbonate buffer system with consumption of HCO$_3^-$.

The ability of the kidney to reclaim and regenerate HCO$_3^-$ prevents the rapid depletion of the available buffer by continued acid production.$^{20,23,24}$

In normal homeostasis, two major mechanisms have been implicated in the generation and reclamation of HCO$_3^-$ by the kidney. The proximal tubular cell secretes free protons (by the NHE3 sodium-hydrogen exchanger) into the glomerular lumen, which combines with filtered HCO$_3^-$ to form H$_2$CO$_3$. In the presence of luminal carbonic anhydrase, H$_2$CO$_3$ is converted to CO$_2$ and water, with the CO$_2$ freely back diffusing into the proximal tubular cell along its concentration gradient. Intracellular carbonic anhydrase then catalyzes the conversion of CO$_2$ and water to HCO$_3^-$ and H$^+$ with the bicarbonate transported to the blood by the serosal NBC (sodium-bicarbonate) transporter, and the H$^+$ is secreted into the lumen to “reclaim” more bicarbonate. The regeneration of bicarbonate can also result from the conversion of CO$_2$ produced through normal tubular cell metabolism into HCO$_3^-$ and H$^+$. The HCO$_3^-$ is transported into the blood, and the H$^+$ passes into the tubular lumen, where it combines with a non-bicarbonate anion like ammonium or phosphate and is excreted in the urine, leading to a net increase in plasma HCO$_3^-$ content and loss of H$^+$. Given these mechanisms, it is estimated that the kidney filters and re-absorbs 4,500 mmol/day of bicarbonate.

The relationship between the liver and the kidney in renal ammoniagenesis and acid-base balance is also important to recognize. Nitrogen metabolism by the liver results in the production of glutamine, urea, and ammonium (NH$_4^+$). The liver normally releases only a very small amount of NH$_4^+$, but it incorporates this nitrogen into urea and glutamine, which are released into the systemic circulation. Renal
ammoniagenesis involves the metabolism of glutamine to generate \( \text{NH}_4^+ \) and increases the renal excretion of \( \text{H}^+ \), leading to an alkalinizing effect on plasma. Acidosis stimulates hepatic glutaminogenesis and inhibits ureagenesis, therefore shifting the balance of nitrogen metabolism toward greater production of glutamine. This greater presentation of glutamine to the kidney increases renal ammoniagenesis, facilitating a greater renal alkalinizing effect.\(^6\),\(^24\) This relationship between liver nitrogen metabolism and renal ammonium excretion appears to be an important mechanism in regulating the metabolic response to acid-base disorders.

Although the traditional physiologic model of acid-base analysis can be useful clinically to identify and diagnose acid-base disorders, viewing it as a mechanistic explanation for the underlying physiology of acid-base disturbances is problematic. The Henderson-Hasselbalch equation, although permitting a quantification of the severity of a respiratory disorder, cannot quantitatively represent the severity of a metabolic acid-base disturbance. It also tells the clinician nothing about the acids contributing to a metabolic disorder other than carbonic acid. Traditional teaching using the physiologic model implies that \( \text{HCO}_3^- \) is independently regulated in response to acid-base disorders; however, \( \text{HCO}_3^- \) cannot be regulated independently of \( \text{Paco}_2 \). The [\( \text{HCO}_3^- \)] in plasma is always increased as the \( \text{Paco}_2 \) increases, but this does not represent a metabolic alkalosis. It is clear that bicarbonate is a dependent parameter in acid-base equilibrium and therefore cannot be presented as a variable that can be manipulated to independently regulate acid-base homeostasis. It is also important to recognize that at a normal plasma pH, the [\( \text{H}_3\text{O}^+ \)] is in the nanomolar range, whereas most acids and strong ions are in the millimolar range. That means that \( \text{H}_3\text{O}^+ \) values are about one-millionth the concentration of other contributors classically attributed to acid-base homeostasis, suggesting that something else must be primarily responsible for acid-base balance.\(^6\),\(^20\) Stated another way, blaming the metabolic acidosis on the finding of a decreased [\( \text{HCO}_3^- \)] is analogous to blaming the bacterial pneumonia on the abnormal chest radiograph. This may be a useful
diagnostic test, but it is not the cause of the disorder.

**BE Model**

To overcome the inability of the Henderson-Hasselbalch equation to quantify the metabolic component of an acid-base disturbance, several methods have been developed, with BE being most widely used. Base excess is defined as the amount of acid or base that must be added to a sample of blood in vitro to restore the pH to 7.40 while the Paco₂ is held constant at 40 mm Hg at 37°C. Because of inaccuracies of this approach in vivo given the variability in Paco₂, the equation was empirically modified to account for an average hemoglobin content across extracellular fluid space, resulting in the SBE. An SBE less than –5 mmol/L is considered to represent a metabolic acidosis, whereas an SBE greater than 5 mmol/L represents a metabolic alkalosis. A negative SBE is often called a base deficit. Although the SBE is able to quantify the change in metabolic acid-base status in vivo, SBE is not regulated by the body and still does not tell the clinician anything about the underlying mechanism of a metabolic acid-base disturbance.⁶,²⁰ The SBE fails as a measure of metabolic acidosis in the patient with hypoalbuminemia, which is almost universal in critically ill patients.⁴,²⁶ The BE can be corrected for changes in albumin, chloride, free water, and Paco₂ to derive a calculation of the BE caused by unmeasured anions (BEUA); however, the calculations are complex for use at the bedside. The BEUA has been found to be superior at identifying lactic acidosis in critically ill patients compared with SBE or uncorrected AG¹,²⁷,²⁸ and is more closely associated with mortality in some studies.²,²⁷ However, the BEUA is not superior to ACAG at detecting unmeasured anions or predicting mortality,²,¹³ is more complex to apply, and is therefore not recommended for routine clinical use in the ICU.

**The Physiochemical or Stewart Model**

This model requires the application of two physical-chemical principles
discussed previously in the analysis of acid-base physiology: electroneutrality and conservation of mass. In addition, all relevant biologic solutions are aqueous and alkaline ([OH\textsuperscript{−}] is greater than [H\textsubscript{3}O\textsuperscript{+}]). The physical-chemical properties of water that are relevant to acid-base physiology include a high dielectric constant, very slight dissociation into H\textsuperscript{+} and OH\textsuperscript{−}, and extraordinarily high molar concentration (around 55.5 M). An aqueous solution provides an almost limitless supply of H\textsuperscript{+}, because of the dissociation of water, and electrolytes and CO\textsubscript{2} present in biologic solutions impart strong electrochemical forces that affect the dissociation of water. Stewart has hypothesized that three independent factors affect acid-base status in vivo: strong ion difference (SID), total weak acid concentration \((A_{TOT})\), and CO\textsubscript{2} content (Paco\textsubscript{2}) of plasma. Changes in one or more of these three independent variables will result in changes in the dependent variables [H\textsubscript{3}O\textsuperscript{+}] (or pH) and [HCO\textsubscript{3}−]. That is, contrary to the physiologic or traditional model, alterations in acid-base status are not caused by changes in [H\textsubscript{3}O\textsuperscript{+}] or [HCO\textsubscript{3}−], and these variables are not regulated to maintain homeostasis but are instead dependent on changes in SID, \(A_{TOT}\), or Paco\textsubscript{2}. In addition, acid-base homeostasis can be explained by mechanisms that regulate SID (metabolic disorders) and Paco\textsubscript{2} (respiratory disorders).\textsuperscript{6,18,19}

Consistent with the traditional model, CO\textsubscript{2} content is an independent predictor of pH and is closely regulated by the respiratory center by influencing minute ventilation. In the ICU setting, fluctuations in minute ventilation may also result from the provision of mechanical ventilation with the possibility of iatrogenic respiratory acid-base disorders. Changes in CO\textsubscript{2} expiration that either exceed or fail to meet CO\textsubscript{2} production rates will result in a primary respiratory alkalosis or acidosis, respectively. A well-controlled and precise match of alveolar ventilation and metabolic CO\textsubscript{2} production will result in a normal Paco\textsubscript{2} of 40 mm Hg (35–45 mm Hg). Several signals may influence the respiratory center regulation of minute ventilation, including Paco\textsubscript{2}, arterial pH, and arterial oxygenation. These variables may be influenced by exercise, anxiety, and wakefulness. This provides a
relatively rapid regulatory mechanism for the regulation of acid-base balance in patients with adequate ventilatory reserve. In the setting of metabolic acidosis or alkalosis, the Paco\(_2\) is adjusted in a predictable way, which is called respiratory compensation. In the setting of a persistent alteration in Paco\(_2\) caused by an underlying respiratory, neurologic, or other disease process leading to a respiratory acidosis or alkalosis, the body will try to correct the acid-base disorder by regulating the independent variable SID, called metabolic compensation.\(^6,9,18,25\)

The SID refers to the difference between the plasma concentrations of fully dissociated cations (Na\(^+\), K\(^+\), Mg\(^2+\), Ca\(^2+\)) and anions (Cl\(^-\) and lactate). Plasma lactate is included because it is almost completely dissociated at a physiologically relevant pH range; it therefore acts as a strong anion. Urate plasma concentration has also been included in the SID calculation; however, it is often unavailable and is quantitatively a small contributor, so it is typically excluded from the calculation. This calculation of SID is also called the apparent SID (SID\(_a\)) because it does not consider weak acids, which are important physiologic buffers to SID:

\[
SID_a = ([Na^+] + [K^+] + [Mg^{2+}] + [Ca^{2+}]) - ([Cl^-] + [lactate])
\]

Concentrations are expressed as milliequivalents per liter, with calcium included as the ionized concentration (calculated or measured). Under normal conditions, the SID\(_a\) is about 40 mEq/L, the positive value consistent with the alkaline state of human plasma, which would be even more alkaline were it not for the presence of dissolved CO\(_2\) in blood. The SID\(_a\) is often much lower than 40 mEq/L in critically ill patients because of alterations in albumin (reducing A\(_{TOT}\)).\(^6,9,18,29\)

The SID has a strong effect on the dissociation of water and therefore the \([H_3O^+]\) and pH. An increasingly positive SID results in a progressive decrease in the weak cation \(H_3O^+\) (increasing pH) to maintain electroneutrality. Likewise, a reduction in SID will lead to an increase in \(H_3O^+\) (decreasing pH). The mechanisms underlying the
regulation of SID are discussed in the paragraphs that follow.

A more complicated calculation developed by Figge et al.\textsuperscript{30} incorporates the role of weak acids (albumin, phosphate) and Paco\textsubscript{2} to the electrical charge equilibrium to derive what is called the effective SID (SID\textsubscript{e}). The SIG is the difference between SID\textsubscript{a} and SID\textsubscript{e} and represents the contribution of unmeasured anions to the SID (e.g., sulfates, ketones, citrate, pyruvate, acetate, and gluconate).\textsuperscript{9,28–30} The recognition of the presence of unmeasured anions has diagnostic relevance for mixed acid-base disorders, and the presence of unmeasured anions has been correlated with increased mortality of critically ill patients.\textsuperscript{2,11,27} The equations for SID\textsubscript{e} and SIG are as follows:

\[
SID_e = 1000 \times 2.46^{11} \times \frac{Paco_2}{(10^{-pH})} + [albumin] \times (0.123 \times pH - 0.631) + [PO_4] \times (0.309 \times pH - 0.469)
\]

In this equation, [albumin] is expressed in grams per deciliter, Paco\textsubscript{2} is expressed in millimeters of mercury, and [PO\textsubscript{4}] is the concentration of plasma phosphates in millimoles per liter.

\[
SIG = SID_a - SID_e
\]

Under normal conditions, the SIG is essentially zero. In the presence of unmeasured strong anions, the SIG is positive, and with accumulation of unmeasured strong cations, the value is negative. A positive SIG is analogous to an elevated ACAG or BE\textsubscript{UA} because all three are affected by the presence of unmeasured strong anions like ketones, sulfates, and other exogenous acids associated with the ingestion of toxins.\textsuperscript{6,24,28,29}

The SID is regulated by changes in the relative plasma concentrations of strong cations and strong anions, with the kidney being the primary organ responsible for adjustments in the SID through the regulation of Cl\textsuperscript{−} balance. A relative loss of Cl\textsuperscript{−} in the urine leads to an increase in the SID and alkalization of the plasma. Although renal
regulation of Na\(^+\) and K\(^+\) could also affect SID and acid-base balance, Na\(^+\) transport is prioritized to maintain intravascular volume and plasma osmolality, and K\(^+\) homeostasis is essential to cardiac and neuromuscular function, so Cl\(^-\) regulation appears to be the predominant renal mechanism to alter SID and maintain acid-base balance without affecting other homeostatic mechanisms.\(^6,24\) The traditional explanation of H\(^+\) excretion being affected by renal ammoniagenesis may not be the true regulatory mechanism because water provides an unlimited source of H\(^+\) on both sides of the renal tubular cell membrane through dissociation of water affected by the composition of the respective aqueous solutions. The importance of renal ammoniagenesis (and hepatic shift to glutaminogenesis described previously) is to increase the excretion of Cl\(^-\) without concomitant losses in Na\(^+\) and K\(^+\) by providing a weak cation (NH\(_4^+\)) to be excreted with Cl\(^-\), emphasizing the importance of electroneutrality as an explanation for many of the factors leading to normalcies and abnormalities in acid-base. The regulation of Cl\(^-\) excretion results in relatively small quantitative changes over time; therefore, subsequent changes in the plasma SID involves a slow process, consistent with the known delayed metabolic compensation in the presence of a persistent respiratory acid-base disorder.\(^6\)

Several acid-base disorders that are common in the ICU can be used to show the important role of alterations of SID on [H\(_3\)O\(^+\)] and explain how the Stewart model provides a much more rational understanding of acid-base pathophysiology than the traditional, bicarbonate-based model. The infusion of a large volume of 0.9% sodium chloride for injection (normal saline) during the resuscitation of critically ill or injured patients can lead to a hyperchloremic metabolic acidosis. Under the traditional model, this has been called a dilutional metabolic acidosis, based on an explanation that dilution of bicarbonate in the extracellular fluid shifts the bicarbonate-carbonate equilibrium to the right, increasing [H\(_3\)O\(^+\)] and leading to an acidemia. According to the Stewart model, both [HCO\(_3^-\)] and [H\(_3\)O\(^+\)] are dependent variables in an aqueous biologic fluid; therefore, the dilutional mechanism is
inadequate to explain the acid-base abnormality. Normal saline provides equal concentrations of Na\(^+\) and Cl\(^-\) (154 mEq/L); however, because of the higher concentration of Na\(^+\) relative to Cl\(^-\) in plasma, the infusion of normal saline leads to a greater relative accumulation of Cl\(^-\) and a reduction in the SID. The electrochemical force of a decreasing SID leads to an increase in \([H_3O^+]\) to maintain electroneutrality and therefore the onset of acidemia. An alternative way to consider this is that for normal saline, the SID is zero (equal concentration of strong cations and strong anions). Therefore, infusing large volumes of a SID 0-mEq/L solution into moderately alkaline plasma (SID approximately equal to 40 mEq/L) will lead to a reduction in the plasma SID and a metabolic acidosis.\(^6\)

Alterations in normal GI function are a common cause of metabolic acid-base disorders in critically ill patients. Under normal conditions, the stomach pumps out large amounts of Cl\(^-\), leading to a decrease of the SID in the lumen and reducing the pH of gastric contents. The loss of the Cl\(^-\) from plasma raises the plasma SID and is consistent with the alkaline tide observed at the start of a meal. The Cl\(^-\) is rapidly reabsorbed at the duodenum, quickly restoring plasma SID and pH. However, if the gastric secretions are lost because of either vomiting or nasogastric suctioning, the plasma SID is persistently increased, leading to a reduction in \([H_3O^+]\) and a metabolic alkalosis. The traditional explanation of gastric H\(^+\) loss leading to a metabolic alkalosis is not plausible given that 1 L of gastric secretions with a pH between 1 and 2 would result in the loss of more total H\(^+\) content than is normally present in all of the extracellular fluid and should therefore lead to a profoundly fatal metabolic alkalosis. In actuality, this modest amount lost from 1 L of vomitus will have a mild effect on acid-base balance, showing that the loss of H\(^+\) cannot be the mechanistic explanation. In addition to the initial increase in SID secondary to Cl\(^-\) loss, the loss of intravascular volume leads to the need to conserve Na\(^+\) and water and maintain K\(^+\) balance. This combination of metabolic alkalosis and intravascular volume loss is commonly termed a contraction alkalosis. Activation of the renin-angiotensin-aldosterone
axis increases sodium reabsorption at the proximal tubular Na-H exchanger (NHE3) and collecting duct Na channels, and activation of hydrogen-ATPase (type B intercalated cells) and K⁺-hydrogen ATPase (type A intercalated cells). The overall effect is to reduce urinary SID, leading to acidification of the urine and maintenance of the metabolic alkalosis. To correct the metabolic alkalosis, it is necessary to replace Na⁺ and Cl⁻ while restoring intravascular volume, replace lost K⁺, and decrease plasma SID. Administering normal saline with supplemental potassium chloride will achieve these goals. This example shows the important interaction between fluid and electrolyte balance and acid-base disorders. In traditional teaching, this is called a chloride-responsive metabolic alkalosis.⁶,¹⁸,²⁵

The third independent variable determining acid-base status in the Stewart model is Aₜₒᵗ, the total concentration of weak acids and their conjugate bases.

\[ A_{TOT} = AH + A^+ \]

The weak acids represented by Aₜₒᵗ are mostly plasma proteins, with albumin being quantitatively most important, and phosphates. Some have suggested that given the independent role of Aₜₒᵗ on acid-base balance, there should be six defined acid-base categories, adding protein-aceous alkalosis and acidosis to the traditional respiratory and metabolic disorders. Although the loss of albumin is associated with an alkalemia and the rapid infusion of albumin will cause a decrease in arterial pH,³¹ there is no evidence that the active regulation of Aₜₒᵗ is physiologically relevant in the maintenance of acid-base balance, so expanding the categories of acid-base disorders is not clinically relevant. Given that hypoalbuminemia is common in the critically ill patient, the Aₜₒᵗ is reduced and is associated with a concomitant reduction in SID to maintain acid-base balance. This apparent compensatory SID response to hypoalbuminemia results in a new normal SID in critically ill patients of about 30–32 mEq/L.⁶ From the perspective of the Stewart model, the regulation of Paco₂ and SID is the major determinant and therapeutic target of acid-base balance. The
\( A_{\text{TOT}} \) should be considered an independent variable influencing acid-base status that is not actively regulated, or manipulated clinically to treat acid-base disorders.\(^{18}\)

Although we believe that the physiochemical model provides a rational explanation of acid-base physiology and mechanistic explanations for common acid-base disorders and their treatments, other experts disagree that there is adequate evidence to accept Stewart’s theories. Kurtz and colleagues provide a comprehensive and sophisticated critique of the issue and conclude that the Stewart and bicarbonate-based approaches provide quantitatively identical results and that the Stewart model provides no diagnostic or prognostic advantage to an approach using the Henderson-Hasselbalch equation. In addition, they argue that the underlying premise that the \([H^+]\) in any given fluid compartment is dependent on SID lacks an experimental basis.\(^{32}\) Thus, although we favor the physio-chemical model proposed by Stewart and others for teaching and clinical purposes, it is important to realize that it remains a controversial and unsettled area of debate.

---

**DIAGNOSIS OF ACID-BASE DISORDERS (STEPWISE APPROACH)**

The physiochemical or Stewart model provides a thorough diagnostic approach to acid-base balance that is also consistent with the mechanisms of acid-base abnormalities in clinical medicine. This understanding of the underlying mechanisms of metabolic disorders leads to a more rational therapeutic approach when intervention is warranted. However, the comprehensive analysis of acid-base status using the Figge-Stewart approach in a critically ill patient requires variables that are often not routinely measured in a simultaneous manner and requires rather complex computations that limit the practical utility of this approach at the bedside. The SBE approach, which accurately quantifies the extent of a metabolic acid-base abnormality, is routinely reported with blood gas results, but SBE is not effective at identifying mixed acid-base disorders without the use of complex corrections of the SBE, which are challenging during routine
clinical care in the ICU. Several investigators have shown that the traditional bicarbonate approach with appropriate adjustment of the AG for hypoalbuminemia, with or without adjustment for lactate, has a diagnostic and prognostic value similar to that obtained with the more complex Figge-Stewart and corrected SBE methods\textsuperscript{2–4,13,26,28,33} and may represent the most practical and easily performed diagnostic approach.\textsuperscript{23,25,29}

An organized, consistent, stepwise approach to the diagnosis of acid-base disorders in critically ill patients is recommended to improve the identification of mixed acid-base disorders, reduce the potential for missing clinically important concomitant problems, and best inform the therapeutic approach to the patient. Although several stepwise approaches have been recommended,\textsuperscript{23} the following approach is recommended for the critically ill patient with a suspected acid-base disturbance (also see Table 1.1).

**Step 1** – Provide a careful clinical evaluation of the patient. Clinical assessment of the patient must include medical history, history of present illness, vital signs, level of consciousness, physical assessment, and medication history. Given this assessment, the expected acid-base abnormalities can be predicted (Table 1.2), and results of the stepwise approach that differ from these expected findings should be suspect and warrant reinvestigation of the patient history and presentation.

**Step 2** – Determine the -emia. This is the easiest step in the process. For practical purposes, if the ABG pH is less than 7.38, the patient can be considered to have an acidemia. If the pH is greater than 7.42, the patient can be considered to have an alkalemia.

**Step 3** – Determine the principal -osis. According to an evaluation of the ABG results, the principal or predominant disorder can normally be determined (Table 1.3). If the patient has a pH in the normal range of 7.35–7.45, the principal disorder will usually be associated with the relative direction of the pH above or below 7.40. An acidemia should be associated with either a decreased \( [\text{HCO}_3^-] \) (metabolic acidosis) or an elevated Paco\textsubscript{2} (respiratory acidosis). An alkalemia will be associated with either an increased \( [\text{HCO}_3^-] \) (metabolic alkalosis) or a decreased
Paco$_2$ (respiratory alkalosis). The secondary or compensatory change in a simple acid-base disorder should be in the same direction as the principal change. For example, a principal metabolic acidosis should be associated with a decrease in [HCO$_3^-$], and a compensatory decrease in Paco$_2$ (Table 1.3). In a complex ICU patient who may have an underlying chronic disorder (e.g., chronic obstructive lung disease), determining the principal disorder may be more challenging because the change from the patient’s normal baseline values is what is relevant to diagnosing an acute change in acid-base status. Without specific data concerning the patient’s baseline status, assumptions based on history and initial serum chemistry results will often need to be made.

</tr>
</tbody>
</table>

Step 4 – If the principal disorder is respiratory, is it acute or chronic? The metabolic regulation of acid-base balance in response to a respiratory disorder takes 2–5 days to reach a new steady state; therefore, a respiratory disorder of less than 2–3 days’ duration is
considered an acute respiratory disorder, whereas a disorder of longer duration is considered chronic from the perspective of metabolic secondary response or compensation. Acute, smaller changes in metabolic status are considered primarily the result of cellular electrolyte shifts, whereas the later and quantitatively greater changes are the result of renal regulation of $\text{Cl}^-$ excretion, leading to compensatory changes in plasma SID. Differentiating acute from chronic classification of respiratory acid-base disorders is necessary to determine whether the degree of compensation is appropriate and therefore determine the presence of simple or mixed acid-base disorders.

Step 5 – Is the secondary or compensatory response appropriate? There are highly conserved patterns between the changes that occur between $\text{Paco}_2$ and $[\text{HCO}_3^-]$ for various principal acid-base disorders that permit the creation of rules to define the secondary or compensatory response to a primary disorder. These compensatory changes in either $\text{Paco}_2$ or $[\text{HCO}_3^-]$ should be considered the patient’s new normal, and values that differ from the new normal are therefore abnormal and represent evidence of a second or concomitant acid-base disorder. Although several different estimations of appropriate compensation for the primary acid-base disorders have been published, Table 1.4 presents the estimations most commonly used in clinical medicine.

Step 6 – Calculate the AG, corrected for albumin. See earlier text for the calculation of AG and ACAG. In critically ill patients, the AG is a poor estimate of unmeasured anions because of the very common presence of hypoalbuminemia; however, the correction for plasma [albumin] greatly improves the ability of the ACAG to detect the presence of “gap” anions. Given the near-universal availability of plasma [lactate] in the diagnostic evaluation of metabolic acidosis, the AG can be further corrected for both albumin and lactate (ALCAG):

\[
\text{ALCAG} = \text{AG} + 2.5([\text{normal albumin}] - [\text{observed albumin}]) - [\text{lactate}]
\]

where albumin concentrations are expressed in grams per deciliter and
lactate concentration in millimoles per liter or milliequivalents per liter. An elevated ALCAG provides evidence of unmeasured anions, which may include toxins (e.g., salicylate, toxic alcohol, and glycols), ketones, sulfates, phosphate, citrate, and d-lactate, among many others. This may provide diagnostic clues toward combined causes of a metabolic acidosis in a critically ill patient. Unmeasured anions are important contributors to metabolic acidosis in critically ill patients and, in some studies, have been correlated with increased mortality. Although some stepwise approaches recommend only calculating the AG when the principal disorder is a metabolic acidosis, failure to calculate the ACAG in the complex critically ill patient may lead to missing the presence of a concomitant elevated AG metabolic acidosis; therefore, routine calculation of the ACAG in critically ill patients is recommended regardless of the principal disorder.

<td>↑ [HCO₃⁻]</td>
</tr>
</tbody>
</table>
Respiratory alkalosis  ↓Paco₂  ↓[HCO₃⁻]

[HCO₃⁻] = plasma bicarbonate concentration (mEq/L); Paco₂ = arterial partial pressure of carbon dioxide (mm Hg).

Step 7 – If the ACAG is elevated, calculate the delta ratio. The delta ratio (also called the delta-delta) is a comparison of the magnitude of the abnormality of the ACAG (delta ACAG) with the change in the [HCO₃⁻] (delta bicarbonate). When calculated as a ratio, the equation is as follows:

$$\text{Delta Ratio} = \frac{ACAG - \text{normal AG}}{\text{Normal } [HCO_3^-] - \text{Measured } [HCO_3^-]}$$

$$= \frac{(ACAG - 12)}{(24 - [HCO_3^-])}$$

where all variables have been previously defined and are expressed as milliequivalents per liter. A delta ratio of 1–2 is consistent with a pure elevated AG metabolic acidosis. A ratio less than 1 is predictive of a concomitant normal AG metabolic acidosis, and a ratio greater than 2 provides evidence of either a concomitant metabolic alkalosis or an appropriately compensated chronic respiratory acidosis. These estimates may be inaccurate in critically ill patients who may have abnormal baseline values because of other underlying processes, and some have raised serious concerns about the accuracy of relying on a single calculation to detect a mixed acid-base disorder. This should be used in the context of a complete understanding of the clinical presentation and history of the patient, together with continued monitoring of changes in the patient status. The delta ratio is just one piece of evidence that needs to be considered with other evidence in a complex ICU patient.³⁴

</tbody>
</table>

Step 8 – If the ACAG is normal in the presence of a metabolic acidosis and the cause is unknown, calculate the urinary anion gap (UAG). Of note, it is uncommon for the critical care clinician to use the UAG or the urinary osmolal gap to evaluate a normal AG metabolic acidosis because the likely causes are typically already known. The UAG is calculated using measured urinary electrolytes:
where all urinary electrolyte concentrations are expressed in milliequivalents per liter. The most common causes of normal AG metabolic acidosis with a negative UAG are infusion of large volumes of normal saline and diarrhea. Proximal renal tubular acidosis (RTA) is also associated with a negative UAG; however, new-onset proximal RTA is not a common cause of acidosis in critically ill patients with no history of RTA. A normal AG metabolic acidosis with a positive UAG may be seen with renal failure, distal RTA, and hypoaldosteronism because of an impaired ability to excrete NH$_4^+$ as NH$_4$Cl. When the UAG may be unreliable (polyuria, urine pH greater than 6.5, and the presence of other urinary anions [e.g., ketones]), the urinary osmolal gap may be used in place of the UAG. A urinary osmolal gap less than 40 mmol/L is equivalent to a positive UAG.$^{23}$

Following this stepwise approach to evaluate an acid-base disturbance in the critically ill patient will normally result in an accurate and complete diagnosis of the acid-base disorders present. A more casual review of the blood gas and chemistry results will often lead to a missed concomitant disorder that may have important diagnostic and therapeutic implications. With practice, this stepwise approach will become routine and can be completed in just a few minutes using simple math and laboratory values commonly available at the bedside. Because of the inherent variability in the measurement of the relevant analytes and the dynamic status of critically ill patients, acid-base analysis is best conducted using results from samples obtained simultaneously.

**CLINICAL SYNDROMES**

The most common acid-base abnormality observed in critically ill patients is an acidosis (metabolic or respiratory). Common reasons for admission to an ICU including sepsis, shock, trauma, renal failure, toxic ingestion, surgical catastrophe, and endocrinologic emergency are associated with a metabolic acidosis, and initial resuscitation or intraoperative management of critically ill patients may lead to
iatrogenic metabolic acidosis, predominantly because of large volumes of intravenous chloride-rich fluids. In addition, respiratory failure secondary to exacerbations of underlying lung disease, neurologic disorders, or toxic drug or substance exposures is associated with an acute respiratory acidosis. The complex nature of critically ill patients and their acute management commonly results in mixed acid-base disorders. Although much of the critical care literature has focused on the recognition, risks, and management of an acidosis in the critically ill patient, recent evidence suggests that metabolic alkalosis is also a common finding during a critical care stay, with most episodes occurring within the first 72 hours of admission to the ICU.5

**Metabolic Acidosis**

As discussed previously, many of the medical and surgical reasons for admission to the ICU and treatments administered in the ICU can be associated with a metabolic acidosis. As shown in Table 1.3, the expected principal finding on an ABG result is a decreased $[\text{HCO}_3^-]$, with a secondary response of decreased $\text{Paco}_2$. Metabolic acidoses have historically been divided into those with an elevated AG and those with a normal AG. As discussed previously, it is critically important that the AG be corrected for serum albumin concentration (ACAG) in ICU patients to improve diagnostic value. An elevated ACAG is analogous to an elevated SIG or BE$_{\text{UA}}$ for the Stewart and BE acid-base models, respectively. For diagnostic purposes, this is a valuable way to categorize metabolic acidosis, given that the elevated AG represents traditionally unmeasured anions that are weak or strong acids responsible for the acidosis and provides valuable clues to the underlying cause and therapeutic approach. Table 1.1 provides a list of common conditions associated with an elevated AG metabolic acidosis. Several acronyms have been used over the years to aid clinicians in remembering the common sources of unmeasured anions when presented with an elevated AG metabolic acidosis, with MUDPILES, GOLD MARRK, and the much simpler KULT being the most popular. Table 1.5 provides the detail of the components of these acronyms.
Lactic acidosis is one of the most common metabolic acidoses presenting in critically ill patients, with the most common causes being shock of any cause, sepsis, severe heart failure, and severe trauma.\textsuperscript{14} The accumulation of lactate, which serves as a strong anion, leads to a reduction in the plasma SID, increasing $[\text{H}_3\text{O}^+]$, and resulting metabolic acidosis. An elevated lactate concentration has a quantitative relationship, both peak lactate and duration of hyperlactatemia, with the risk of mortality in critically ill patients,\textsuperscript{14} and resuscitative measures leading to a reduction in blood lactate levels have been associated with improved clinical outcomes.\textsuperscript{15} The l-isomer of lactate, as primarily the byproduct of anaerobic cellular metabolism, is the physiologically relevant form of lactate. However, d-lactate accumulation can be clinically important in the ICU setting after intravenous propylene glycol administration (e.g., lorazepam infusions), toxic ingestions of propylene glycol,\textsuperscript{35,36} and ischemic bowel.\textsuperscript{8} Routine clinical laboratory assays detect and report only l-lactate concentrations, so the presence of d-lactate represents an unmeasured anion that can contribute to a metabolic acidosis.

Pyruvate is generated primarily by cellular anaerobic glycolysis under hypoxic conditions and is reversibly converted to lactate by the following reaction:

\[
\text{Pyruvate} + \text{NADPH} + H^+ \leftrightarrow \text{Lactate} + \text{NAD}^+
\]

An adult human generates about 20 mmol/kg of lactate daily. Lactate is normally reconverted to pyruvate, which is then metabolized by mitochondrial oxidation within LDH-rich tissues including the liver (70%), kidneys, and skeletal muscle. Metabolism through the Cori cycle leads to the formation of glucose (gluconeogenesis). The tricarboxylic acid cycle and oxidative phosphorylation leads to the generation of CO\textsubscript{2} and water, which can lead to bicarbonate generation. Normal equilibrium of production and metabolism of lactate-pyruvate leads to low steady-state plasma concentrations of lactate; however, rapid increases in lactate production during various causes of tissue hypoxia can lead to sharp increases in blood lactate concentrations. The combination of decreased mitochondrial oxidative phosphorylation secondary to tissue hypoxia, microcirculatory failure, and tissue acidemia will also decrease lactate clearance, contributing to the increase in blood lactate. Other potential contributors to hyper-lactatemia in critically ill patients may include underlying chronic liver disease, fulminant hepatic failure, renal failure, drugs that impair normal oxidative phosphorylation (e.g., antiretroviral agents, propofol, and metformin), and physiologic stress (e.g., severe trauma, pheochromocytoma) or drugs (e.g., epinephrine, albuterol) that cause β\textsubscript{2}-adrenoceptor stimulation, leading to increased aerobic glycolysis independent of tissue hypoxia.\textsuperscript{8,14} High-dose catecholamine infusions during treatment of shock can aggravate

\[\text{Ketoacidosis} \quad \text{Uremia} \quad \text{Lactate} \quad \text{Toxins}\]

\[\text{Revised by some to MUDPILERS, with the “R” representing rhabdomyolysis.}\]
hyperlactatemia by β2-adrenoceptor stimulation; this has especially been true with the use of epinephrine vasopressor therapy.27,37–39

Traditionally, lactic acidosis has been categorized into type A and type B; however, in a complex critically ill patient, differentiating type A from type B is difficult, artificial, and probably clinically irrelevant.8,14

An elevated serum AG, even with correction for plasma [albumin], lacks adequate sensitivity and specificity for the diagnosis of lactic acidosis.4,33 In the setting of sepsis and other clinical conditions potentially associated with lactic acidosis, the current recommendation is to directly measure blood lactate concentrations rather than rely on a calculation of unmeasured anions like the AG or ACAG.14,40 It is also important to recognize that in cases of metabolic acidosis with confirmed hyperlactatemia, there is often a significant contribution to the acidemia by other unmeasured anions, with studies showing that lactate contributes only a portion of the increased AG.2,27,28,33 An elevation in unmeasured anions other than lactate has been associated with increased mortality,11,27,28,33,41 but the finding has not been consistent.1–3,13 Gunnerson et al.41 reported the results of a retrospective study of 851 ICU patients, of which 584 had evidence of a metabolic acidosis. The patients were classified according to the primary anion contributing to metabolic acidosis as lactate, chloride, or other unmeasured anions (elevated SIG). To be classified as lactic or SIG acidosis, at least 50% of the contribution had to be from that factor, with many patients having a combined lactate and SIG contribution to the metabolic acidosis. The mortality rate for lactic acidosis was 56%, for hyperchloremic acidosis 29%, and for SIG acidosis 39% (p<0.001). Multivariate analysis found that independent predictors of mortality were serum lactate, SIG, serum phosphate, and age. Clearly, the contributors to metabolic acidosis in critically ill patients with hyperlactatemia can be complex, and the relevance of these combined contributors to metabolic acidosis on overall morbidity and mortality is uncertain.

Ketoacidosis is an elevated AG metabolic acidosis caused by the overproduction and accumulation of organic acids, most commonly secondary to diabetes mellitus. Other forms of ketoacidosis in critically
ill patients are alcoholic and starvation ketoacidosis, although these are normally mild to moderate in severity. Although the overall attributable mortality to diabetic ketoacidosis (DKA) in adult patients is low (less than 1%), the mortality is greatest in older adults and patients with severe underlying illnesses. Although DKA is most common in patients with type 1 diabetes, about one-third of DKA episodes occur in type 2 diabetes with concomitant severe illness or injury caused by trauma, infection, or surgery.42

The combination of decreased effective insulin concentrations and increased counter-regulatory hormones (glucagon, cortisol, catecholamines, and growth hormone) results in hyperglycemia and ketosis. Lipolysis of adipose tissue leads to the release of free fatty acids into the circulation and hepatic fatty acid metabolism to ketones (β-hydroxybutyrate and acetoacetate).42,43 This causes an increase in circulating ketones, which act as strong anions reducing the SID, leading to an increase in $[\text{H}_3\text{O}^+]$ and an elevated AG metabolic acidosis. In addition to the acid-base disturbance, osmotic diuresis and natriuresis secondary to hyperglycemia leads to extracellular volume loss. An increase in plasma [albumin] secondary to the contraction of intravascular volume needs to be considered when evaluating the AG.43 Administering normal saline to treat the hypovolemia associated with DKA may result in a concomitant hyperchloremic metabolic acidosis, as discussed in the text that follows.

The most common precipitating factor for DKA is infection. Other precipitants include discontinuation of insulin therapy, cerebrovascular accident, pancreatitis, myocardial infarction, and new-onset type 1 diabetes. Patients with DKA present with a history of polyuria, polydipsia, nausea and vomiting, dehydration, weakness, and mental status changes. Physical findings include skin and mucous membrane changes consistent with dehydration, Kuss-maul respirations, diffuse abdominal pain, tachycardia, and hypotension. Metabolic acidosis, elevated AG, and the presence of circulating ketones in blood are diagnostic of DKA. A laboratory method that can detect both acetoacetate and β-hydroxybutyrate is preferred because the classic nitroprusside reaction does not detect β-hydroxybutyrate, which is the
main ketone present in DKA.\textsuperscript{42} Alcoholic and starvation ketoacidosis may be missed using the nitroprusside reaction for serum or urinary ketones because $\beta$-hydroxybutyrate is the relevant circulating ketone body for these forms of ketoacidosis.\textsuperscript{8,23}

Acute and chronic renal failure are important causes of an elevated AG metabolic acidosis in critically ill patients. Unlike lactic acidosis and ketoacidosis, which are caused by increased production of organic acids, the acidosis caused by renal dysfunction is the result of decreased excretion of the inorganic sulfates and phosphates, primarily caused by the normal metabolism of dietary proteins and amino acids. In the setting of renal failure, an increase in unmeasured anions as reflected by a positive ALCAG or SIG is expected. Renal failure can also cause a normal AG acidosis as the kidneys lose the ability to secrete NH$_4$Cl. Metabolic acidosis is of greater concern as glomerular filtration rate decreases to less than 20 mL/minute. Acute renal failure may also contribute to lactic acidosis caused by decreased renal clearance of lactate.\textsuperscript{8,20}

Toxic ingestions of ethylene glycol, methanol, acetone, and salicylate lead to an elevated AG metabolic acidosis. The presence of unmeasured anions in the setting of a metabolic acidosis in a recently admitted critically ill patient should raise concerns for a potential poisoning and trigger appropriate diagnostic testing. For suspected methanol or ethylene glycol ingestions, the osmolar gap (the difference between the measured and calculated osmolarity) is a useful screening tool. An osmolar gap greater than 10 mOsm/L, corrected for blood ethanol concentration, is considered abnormal.\textsuperscript{8,9}

A normal AG, hyperchloremic metabolic acidosis is a common finding in the critically ill patient. The most common causes are resuscitation with chloride-rich, crystalloid intravenous solutions (primarily normal saline) and diarrhea. It is not uncommon that a hyperchloremic metabolic acidosis is concomitant with other acid-base disorders and is often the result of the treatment for the underlying cause of an initial elevated AG metabolic acidosis. As discussed previously, the metabolic acidosis secondary to the administration of normal saline is not mechanistically a dilutional acidosis caused by the
expansion of extracellular fluid volume and the resulting dilution of a fixed quantity of bicarbonate, but is instead secondary to a reduction in the SID caused by the accumulation of chloride.\(^6,8,25,44,45\)

Historically, the mechanistic explanation for hyper-chloremic metabolic acidosis caused by severe or persistent diarrhea has been the loss of GI bicarbonate. However, it is the loss of strong cations (\(\text{Na}^+\), \(\text{K}^+\)) in excess of strong anions (\(\text{Cl}^-\)) in the diarrheal fluids that decreases the plasma SID leading to an acidosis.\(^6,25\) The changes in \([\text{HCO}_3^-]\) and \([\text{H}_3\text{O}^+]\) are secondary (dependent) to the primary (independent) change in the SID.

Hyperchloremic metabolic acidosis secondary to normal saline administration and diarrhea are both associated with a negative UAG because of an increased excretion of urinary ammonium chloride in response to the acidosis. Other, less common causes of a hyperchloremic acidosis with a negative UAG are proximal (type 2) renal tubular acidosis, ureteral diversion, loss of small bowel or pancreatic secretions, and some medications or toxins (e.g., toluene, ifosfamide, tenofovir, topiramate, and carbonic anhydrase inhibitors). Hyperchloremic metabolic acidosis with a positive UAG may be associated with renal dysfunction and distal (types 1 and 4) renal tubular acidosis.\(^23\) Type 4 renal tubular acidosis caused by hypoaldosteronism may be observed with high-dose steroid therapy because of the mineralocorticoid effects of the drug.

The secondary response, often termed a compensatory response, to a metabolic acidosis is an increase in minute ventilation and a resulting decrease in Paco\(_2\). The equation to describe this relatively well-preserved relationship is provided in Table 1.4, which assumes that the patient is able to mount and maintain a secondary respiratory response. Although this is often called a compensatory respiratory alkalosis, it is best to think of this secondary response as the new normal Paco\(_2\) for the patient, given the extent of the primary metabolic disorder, and that a Paco\(_2\) different from this new normal range is representative of a mixed metabolic-respiratory disorder. It is unusual that the degree of the secondary respiratory response is adequate to completely normalize or correct the acidemia caused by the metabolic
disorder; therefore, the pH will typically remain in the lower end of the normal range with an appropriate secondary response. Patients with an underlying respiratory disorder (e.g., chronic obstructive lung disease) may have an abnormal Paco\(_2\) at baseline, which needs to be considered when evaluating the appropriateness of the patient’s response to a primary metabolic disorder, and will often limit the ability of the patient to maintain an adequate secondary response.

The treatment of the ICU patient with a metabolic acidosis should be primarily aimed at the treatment of the underlying disorder. Effective treatment of the predominant cause should lead to resolution of the metabolic acidosis. For patients presenting with sepsis, shock, severe heart failure, or other causes of tissue hypoxia leading to a predominantly lactic acidosis, the focus is on restoring hemodynamics with fluids, vasoactive and inotropic agents as indicated, treatment of any underlying infection, and other supportive measures as needed.\(^{14}\) A reduction in lactate production and restoration of normal lactate-pyruvate equilibrium will lead to an increased SID because of the metabolism of excess lactate, reduction in [H\(_3\)O\(^+\)], and resolution of the elevated AG metabolic acidosis. As inferred previously, the choice of treatment for these complex ICU patients may contribute to worsening acidemia and increases in lactate, so the approach to restoring hemodynamic stability may be important. Overreliance on normal saline for fluid resuscitation may exacerbate the acidemia because of a superimposed hyperchloremic metabolic acidosis, and the use of epinephrine for vasopressor support may increase blood lactate concentrations because of a concomitant type B lactic acidosis secondary to an increase in aerobic glycolysis.\(^{37–39}\)

The treatment of DKA requires the administration of insulin, restoration of intravascular volume, and careful management of electrolyte disturbances. In addition, underlying triggers for DKA (e.g., infection) require prompt management. The continuous intravenous administration of insulin is the cornerstone of the treatment of DKA, although recent studies have shown a potential role for subcutaneous rapid-acting insulin analogs. Insulin therapy will suppress the production of ketone bodies, and the metabolic clearance of circulating ketones...
will lead to an increase in the SID and resolution of the acidosis. Insulin therapy also leads to the resolution of hyperglycemia. A detailed discussion of the management of DKA is beyond the scope of this chapter, and the reader is referred to recent guidelines of the management of DKA in adult\textsuperscript{42} and pediatric patients\textsuperscript{46}.

An elevated AG metabolic acidosis secondary to toxins will require appropriate management to minimize continued absorption and enhance clearance of the toxin and administration of appropriate antidotes or metabolic blockers to minimize the impact of the toxic ingestion. A detailed discussion of the management of common drug overdoses and toxic exposures appears in chapter 39, “Medication Withdrawal in the ICU.” An elevated AG metabolic acidosis secondary to severe renal dysfunction will typically require renal replacement therapy in the critically ill patient, and severe metabolic acidosis is one of the indications to acutely initiate renal replacement therapy (see Chapter 28, “Management and Drug Dosing in Acute Liver Failure”).

The treatment of hyperchloremic metabolic acidosis secondary to the use of chloride-rich intravenous solutions usually involves discontinuing the implicated intravenous solution and, if continued fluid administration is indicated, switching to a balanced or more alkaline solution (e.g., lactated Ringer or Plasma-Lyte solutions). See the following text for a more detailed discussion of intravenous fluid choices and their potential influence on acid-base disorders. For patients with severe diarrhea or other GI fluid losses leading to hyperchloremic metabolic acidosis, treatment involves therapies aimed at the underlying diarrhea as well as restoration of fluid losses using a balanced or alkalinizing intravenous solution with careful monitoring and management of electrolyte disorders.

Severe metabolic acidosis characterized by a pH less than 7.2 or $\left[\text{HCO}_3^-\right]$ less than 8 mEq/L may be associated with the direct adverse effects of decreased cardiac contractility, poor regulation of vascular tone with hypotension, cardiac arrhythmias, pulmonary hypertension, central nervous system (CNS) dysfunction, and other serious adverse metabolic consequences.\textsuperscript{47,48} General treatment of severe metabolic acidosis has been advocated as a temporizing measure while specific
treatment of the underlying condition is being pursued; however, strong evidence of the benefit of treatment is lacking. For DKA, the current recommendation for the general treatment of acidosis is a pH less than 6.9. Treatment goals should be partial correction of the acidosis to pH greater than 7.2, or $[\text{HCO}_3^-]$ greater than 8–10 mEq/L, not normalization of the acidemia. The goal in the treatment of DKA is a pH greater than 7.0. The mainstay for the general treatment of metabolic acidosis in critically ill patients is sodium bicarbonate injection, available commercially as a 1-mEq/mL solution. The long-standing teaching under the physiologic or bicarbonate-centered model is that exogenous sodium bicarbonate replaces plasma bicarbonate, leading to improvement in the acidosis, and the recommended dose of sodium bicarbonate has been estimated using a calculation of the base deficit. However, the explanation from a physiochemical model perspective is that sodium bicarbonate provides a strong cation ($\text{Na}^+$) in the absence of a strong anion ($\text{HCO}_3^-$ is a weak anion), leading to an increase in the SID and correction of the metabolic acidosis. For example, an intravenous solution containing 75 mEq/L of sodium bicarbonate added to 0.45% sodium chloride for injection (½ normal saline; 77 mEq/L of sodium chloride) has a SID of 75 mEq/L and, when administered intravenously, will result in an increase in the plasma SID and therefore have an alkalinizing effect. In vivo, the $[\text{HCO}_3^-]$ is dependent on the independent factors SID, $A_{TOT}$, and $\text{Paco}_2$, and not on the amount of exogenously administered $\text{HCO}_3^-$. The dose of sodium bicarbonate has traditionally been calculated to determine the amount needed to raise the $[\text{HCO}_3^-]$ to some desired concentration according to an estimate of the bicarbonate space. Although the bicarbonate-centered approach to this estimate is physiologically incorrect, the estimation is likely still reasonable. To be conservative, the bicarbonate space is estimated to be 50% of the total body weight. The simplified equation is as follows:

$$\text{Sodium Bicarbonate Dose} = [\text{HCO}_3^-]_{\text{desired}} - [\text{HCO}_3^-]_{\text{actual}} \times (BW \times 0.5)$$
where the sodium bicarbonate dose is in milliequivalents, \([\text{HCO}_3^-]\) values are in milliequivalents per liter, and BW is body weight in kilograms.\(^8\),\(^23\),\(^47\),\(^48\) Although this equation has been widely recommended for many years, most ICU clinicians will empirically administer 50–100 mEq of sodium bicarbonate as a slow infusion while closely monitoring response. Additional sodium bicarbonate will be administered as indicated by pH response. Bolus administration should be reserved for severe, life-threatening acidosis, and most patients should be treated with a slow infusion over 2 hours or more. Common solutions are to add 75 mEq/L of sodium bicarbonate to 1 L of \(\frac{1}{2}\) normal saline or 150 mEq/L of sodium bicarbonate added to 1 L of sterile water for injection to provide an isotonic solution with a SID of 75 mEq/L or 150 mEq/L, respectively. Administering sodium bicarbonate as an infusion will reduce the risk of potential adverse effects.\(^48\)

The potential adverse effects of treatment with sodium bicarbonate are hypernatremia and hyperosmolarity, extra-cellular fluid volume overload, overshoot alkalosis, worsening intracellular acidosis because of \(\text{CO}_2\) production, reduction in ionized calcium leading to impaired cardiac contractility, hypokalemia, and increased risk of cerebral edema in children with DKA.\(^46\)–\(^48\) The risk of overshoot alkalosis is thought to be greatest in the treatment of metabolic acidosis secondary to organic acids (lactate and ketones) because of the metabolism of these anions leading to an increase in \([\text{HCO}_3^-]\).\(^47\),\(^48\) However, if it is accepted that the \([\text{HCO}_3^-]\) is a dependent parameter, and not an independent determinant of acid-base status, this argument lacks rationale. Administering sodium bicarbonate to a target pH of 7.2 or less should avoid the risk of overtreatment leading to metabolic alkalosis. The aggravation of intracellular acidosis after the administration of sodium bicarbonate is believed to be the result of the formation of \(\text{CO}_2\), which can readily permeate the cell and increase the intracellular \(\text{CO}_2\) content leading to worsening acidosis. In theory, this is more likely to occur with rapid administration of sodium bicarbonate, a high hematocrit, and poor tissue clearance of \(\text{CO}_2\) during low-flow
states. However, if 100 mEq of sodium bicarbonate were administered over 1 hour and led to a 100% formation of CO\(_2\) (i.e., 100 mmol), this would represent about a 16% increase over normal CO\(_2\) generation by an adult, which, unless there was severe impairment of pulmonary CO\(_2\) excretion, or permissive hypercapnia for severe acute lung injury, should not have a significant effect on intra-cellular CO\(_2\) content. One study of treating mild intraoperative hyperchloremic metabolic acidosis with 128 plus or minus 18 mEq of sodium bicarbonate administered over 20 minutes required a transient increase in minute ventilation by 40% to maintain end tidal Pco\(_2\) at baseline, whereas after tris-hydroxymethyl aminomethane administration, the minute ventilation was decreased by 60%, suggesting that relatively rapid administration of sodium bicarbonate can lead to transient increases in CO\(_2\) formation. Administering low to moderate doses of sodium bicarbonate as a slow infusion over 1 hour or more is unlikely to have an important impact on CO\(_2\) retention and intracellular acidosis in a patient with adequate ventilation and CO\(_2\) excretion. Given the absence of a strong argument to routinely administer sodium bicarbonate and the potential for adverse effects, using sodium bicarbonate for severe acidosis is an individualized decision based on underlying cardiovascular disease, evidence of adverse effects of acidosis, ability to tolerate a fluid load from an isotonic infusion of sodium bicarbonate, and the theoretical risk of CO\(_2\) retention and intracellular acidosis. During sodium bicarbonate treatment, careful monitoring of ionized calcium and potassium concentrations is recommended.

Tris-hydroxymethyl aminomethane is an alternative buffer that was developed to overcome some of the limitations of sodium bicarbonate. Tris-hydroxymethyl amino-methane is administered as a 0.3M solution and is proposed to act as a proton acceptor because of its ammonia moiety, leading to a decrease in \([H_3O^+]\) and an increase in pH in patients with metabolic acidosis. Because there is no production of CO\(_2\) based on this mechanism and an un-ionized portion of the tris-hydroxymethyl amino-methane can penetrate intracellularly, a proposed
advantage of tris-hydroxymethyl aminomethane is that it does not worsen intracellular pH. When given in equivalent doses, tris-hydroxymethyl aminomethane appears to be as effective as sodium bicarbonate at improving extracellular acid-base parameters.\textsuperscript{8,47,48,50,53} In a trial comparing tris-hydroxymethyl aminomethane and sodium bicarbonate for the treatment of intraoperative hyperchloremic metabolic acidosis, Rehm and Finsterer showed that the change in $[\text{HCO}_3^-]$ was correlated with a reduction in the SIG because of the increase in an unmeasured cation after the administration of tris-hydroxymethyl aminomethane, presumably the protonated form of tris-hydroxymethyl aminomethane.\textsuperscript{53} Therefore, the mechanism of action of tris-hydroxymethyl aminomethane for correcting acidosis can be explained by the Stewart model, with protonated tris-hydroxymethyl aminomethane acting as a strong cation leading to an increase in the SID.\textsubscript{e} The recommended dose of tris-hydroxymethyl aminomethane is based on a calculation incorporating the base deficit:

$$\text{THAM dose (mL)} = \text{body dry weight} \times ([\text{HCO}_3^-]_{\text{dest}} - [\text{HCO}_3^-]_{\text{acrit}}) \times 1.1$$

where THAM is tris-hydroxymethyl aminomethane, dry body weight is in kilograms and [HCO\textsubscript{3}^-] values are in milliequivalents per liter.

Tris-hydroxymethyl aminomethane undergoes renal elimination; therefore, it is typically not recommended with a creatinine clearance of less than 30 mL/minute/1.73 m\textsuperscript{2}. Potential adverse effects associated with trishydroxymethyl aminomethane are extravasation injuries, hypoglycemia, respiratory depression, and hyperkalemia. Even though tris-hydroxymethyl aminomethane has been in clinical use since 1959, its role in managing metabolic acidosis remains uncertain and limited given its lack of demonstrated superiority to sodium bicarbonate, its major benefits being primarily theoretical, and its higher cost.\textsuperscript{48}

Sodium acetate injection is an alternative to sodium bicarbonate that has been most widely used in parenteral nutrition, in balanced intravenous solutions (e.g., Plasma-Lyte), and during times of sodium bicarbonate shortages. To be an effective buffer by increasing SID, the
acetate must be metabolized, which proceeds readily. In one comparative study of different buffer replacement solutions during continuous renal replacement therapy in critically ill patients, the use of a sodium acetate–based solution was less effective at improving acid-base status than either a lactate- or a bicarbonate-based replacement solution and was associated with less improvement in hemodynamic parameters, raising concerns that sodium acetate may be a less effective treatment for acidosis in critically ill patients with acute renal failure. Comparative studies of sodium acetate and sodium bicarbonate as a general treatment for severe metabolic acidosis are unavailable; therefore, sodium acetate should not be considered a primary alternative unless sodium bicarbonate is unavailable.

**Metabolic Alkalosis**

Although metabolic alkalosis is less common and less well studied in critically ill patients, it is not rare and may often be present with, and masked by, a concomitant metabolic acidosis. In one large retrospective study, 29.3% of critically ill patients had at least one $[\text{HCO}_3^-]$ greater than 30 mEq/L during their ICU stay. An increased $[\text{HCO}_3^-]$ was associated with a longer ICU length of stay, more days on mechanical ventilation, and a greater hospital mortality rate. The most common causes of a metabolic alkalosis in critically ill patients are chloride-wasting diuretic use and loss of upper GI fluids because of vomiting or nasogastric suctioning. Less common causes are chloride diarrhea or mineralocorticoid excess. Metabolic alkalosis is characterized by an elevated $[\text{HCO}_3^-]$, with an increased Paco$_2$ as a secondary or compensatory response (see Table 1.3). Metabolic alkalosis is further subdivided into those that are chloride responsive and those that are chloride resistant. A chloride-responsive metabolic alkalosis is typically associated with a spot urinary chloride concentration less than 25 mEq/L (although this test is not usually necessary in the ICU to make the diagnosis given the clinical history) and is responsive to treatment with normal saline. However, in the face of continued loop diuretic use, the urinary chloride concentration may
be elevated. Most metabolic alkaloses in critically ill patients are chloride responsive. Usual causes of new-onset chloride-resistant metabolic alkaloses are uncommon in the ICU, with the possible exception of iatrogenic mineralocorticoid excess.

As described previously, the loss of upper GI secretions because of vomiting or nasogastric tube drainage leads to a loss of Cl\(^-\), an increase in plasma SID, and the onset of metabolic alkalosis. The loss of intravascular volume and activation of the renin-angiotensin-aldosterone axis leads to further acidification of the urine and maintenance of the alkalotic state. The frequent use of loop diuretics in the critically ill patient may also lead to the development of a metabolic alkalosis. Loop diuretics inhibit the sodium-potassium-chloride (NKCC) cotransporter in the thick ascending limb of the loop of Henle, leading to a greater net loss of Cl\(^-\) than Na\(^+\) in the urine. The greater loss of Cl\(^-\) leads to an increase in plasma SID and the onset of metabolic alkalosis. Thiazide diuretics inhibit the sodium-chloride cotransporter of the distal convoluted tubular cells, with a relatively greater loss of Cl\(^-\) than Na\(^+\) from the extracellular fluid, leading to an increase in plasma SID and metabolic alkalosis. Aggressive diuresis may lead to the loss of intravascular volume, and activation of the renin-angiotensin-aldosterone axis will serve to maintain the alkalosis as described previously.

The treatment of a metabolic alkalosis secondary to chloride loss is primarily aimed at treating the underlying process (e.g., vomiting), discontinuing diuretics, and replacing intravascular volume with normal saline. Potassium depletion can contribute to metabolic alkalosis; therefore, correction of any potassium losses with potassium chloride is also required. There is a limited role for pharmacologic management of metabolic alkalosis.

Acetazolamide is a carbonic anhydrase inhibitor that can be administered intravenously for the treatment of metabolic alkalosis in critically ill patients. Traditional teaching is that by inhibiting carbonic anhydrase, acetazolamide interferes with regeneration and recovery of urinary bicarbonate and increases urinary bicarbonate losses, leading to a decrease in plasma \([\text{HCO}_3^-]\) and resolution of the
metabolic alkalosis. This is not consistent with the Stewart model, where \( \text{HCO}_3^- \) is a dependent parameter and does not have an independent role in regulating acid-base status. Moviat and coworkers showed that a single intravenous dose of acetazolamide 500 mg effectively corrected metabolic alkalosis in critically ill patients through a reduction in SID secondary to a significant increase in urinary \( \text{Na}^+ \) excretion without a concomitant \( \text{Cl}^- \) loss. For patients with a clinically significant metabolic alkalosis and no clinical evidence of intravascular volume depletion, acetazolamide is a reasonable and effective first treatment option when intravascular volume expansion is not indicated or wanted. The clinical evidence suggests that a single intravenous dose of 500 mg is as effective as repeated doses and, in the absence of ongoing chloride loss, has a persistent effect for at least 72 hours.\textsuperscript{56,57} In our clinical experience, a repeat dose after 48–72 hours, if needed, may give additional response, but usually less than the initial dose. Routine, scheduled doses in critically ill patients are not recommended.

Chloride replacement is the preferred treatment for most patients with chloride-responsive metabolic alkalosis. Most commonly, ICU patients with metabolic alkalosis will have clinical evidence or history consistent with intravascular volume depletion; therefore, the treatment of choice is intravenous normal saline, often with supplemental potassium chloride. As discussed previously, normal saline provides 154 mEq/L of \( \text{Na}^+ \) and \( \text{Cl}^- \) with a SID of zero. Therefore, it provides relatively more \( \text{Cl}^- \) than \( \text{Na}^+ \) compared with plasma electrolyte concentrations, leading to a reduction in the plasma SID and resolution of the metabolic alkalosis. In the setting of a chloride-responsive metabolic alkalosis, normal saline is an effective chloride replacement solution. In addition, the reestablishment of an effective circulating volume will reverse the effects of the renin-angiotensin-aldosterone axis on sustaining urinary \( \text{Cl}^- \) losses.

Continuous infusion or regularly scheduled doses of loop diuretics to treat excessive extracellular volume in a stable ICU patient to facilitate weaning from mechanical ventilation and reduce edema will often result in a metabolic alkalosis that may be moderate to severe. In the
absence of overt signs of intravascular volume depletion (e.g., hemodynamically stable and unchanged or improving renal function tests), it may be desired to continue aggressive diuresis; however, the metabolic alkalosis becomes the major barrier to continued treatment. Although administering normal saline would effectively treat the metabolic alkalosis, this would be counterproductive to the goals of removing excess extravascular fluids and reducing peripheral edema. Although acetazolamide may be an effective way to extend the duration of diuresis, the continued chloride loss caused by loop diuretics often leads to a limited and transient effect of the drug. Alternative chloride replacement options can be very useful to manage this clinical dilemma.

Dilute hydrochloric acid (0.1N or 0.2N) intravenous solutions have been used clinically for several decades to treat moderate to severe metabolic alkalosis.\textsuperscript{58–63} These solutions have the advantage of providing a strong anion (Cl\textsuperscript{−}) in the absence of a strong cation, leading to a significant reduction in SID and improvement in the metabolic alkalosis without providing expansion of intravascular volume. Contrary to traditional teaching, the mechanism of action in the treatment of metabolic alkalosis is chloride replacement, not the provision of H\textsuperscript{+}. The SID of a 0.1N hydrochloric acid solution is –100 mEq/L, and the SID of the 0.2N solution is –200 mEq/L, so the volumes required to replace chloride are not excessive. There are no commercially available hydrochloric acid intravenous solutions, so they must be prepared extemporaneously from concentrated hydrochloric acid sterilized using cold filtration and added to sterile water for injection in glass containers. Because of the risk of severe extravasation injury with tissue necrosis,\textsuperscript{64,65} it is strongly recommended that hydrochloric acid be infused through a central line using the distal port only after the position of the catheter has been confirmed radiographically. The dose can be estimated by calculating the chloride deficit or BE. The chloride deficit equation is as follows:

\[
Cl^- \text{ Deficit } = (0.2 \text{ L/kg } \times \text{ BW}) \times (103 - \text{ observed serum } Cl^-)
\]
where Cl\(^{-}\) deficit is milliequivalents, observed serum Cl\(^{-}\) is milliequivalents per liter, and BW is body weight in kilograms.\(^{66}\) It is usually recommended to administer the calculated dose over 12–24 hours. However, if there are ongoing chloride losses, the calculation of the required dose will be inaccurate. In most cases, careful laboratory monitoring and adjustment of the dose to achieve the desired rate and extent of correction is usually adequate. The infusion can be started at 40–80 mEq/hour (40 mL/hour of the 0.1N or 0.2N solution, respectively) and adjusted as needed. If precautions are taken to minimize the risk of extravasation, hydrochloric acid infusions are well tolerated with very few reported adverse effects.\(^{58–63}\)

Ammonium chloride is an alternative chloride replacement solution. It is available as a 100-mEq/20 mL solution for intravenous administration after further dilution in a compatible intravenous solution for the treatment of severe metabolic alkalosis. The dose is estimated by calculating the chloride deficit and replacing about one-half of the calculated dose over 12 hours, at a rate not to exceed 1 mEq/minute. Additional ammonium chloride can be administered as indicated. Ammonium chloride should be administered cautiously to patients with renal or hepatic dysfunction, and it is contraindicated in the presence of severe renal or hepatic impairment. Exacerbation of urea accumulation and uremic symptoms can be observed in the setting of renal failure. Hepatic dysfunction can lead to the accumulation of ammonia and CNS toxicity, including confusion, irritability, seizures, and coma.\(^{66}\)

**Respiratory Acidosis**

An elevation in Paco\(_2\) because of the failure to excrete CO\(_2\) at a rate equivalent to production results in a respiratory acidosis. The Paco\(_2\) is an independent variable in acid-base disorders, and the resulting change in \([H_3O^+]\) (or pH) depends on the overall changes in Paco\(_2\) and SID, assuming that A\(_{TOT}\) is not altered to regulate acid-base status. The evaluation and management of respiratory acidosis is separated into acute versus chronic according to the clinical history. The
secondary response is evidenced by a change in $[\text{HCO}_3^-]$ in the same direction as $\text{Paco}_2$ (Table 1.3) but is secondary to a positive change in SID.\(^{67}\) The quantitative change in SID and $[\text{HCO}_3^-]$ is related to the acute versus chronic nature of the respiratory acidosis (see Table 1.4). The smaller change during an acute respiratory acidosis is believed to be secondary to a cellular shift of electrolytes, whereas the changes with a more prolonged respiratory acidosis (typically 3–5 days) are caused by the regulation of $\text{Cl}^-$ by the kidney.\(^{67}\) The secondary change is inadequate to fully correct the acidemia caused by the primary respiratory acidosis in most cases.

The causes of a respiratory acidosis can be divided into acute or chronic parenchymal lung or airway diseases, neuromuscular disorders, perfusion abnormalities, CNS-mediated respiratory failure, and iatrogenic ventilatory complications (see Table 1.6). Patients may present from being asymptomatic in the setting of stable, chronic hypercapnia to having serious neurologic signs including mental status changes, stupor, and seizures with an acute and significant rise in $\text{Paco}_2$. With acute, severe hypercapnia and acidemia, there may be a decline in cardiac output and hypotension because of reduced vascular resistance.\(^{66}\)

Treatment of a respiratory acidosis is dependent on both the chronicity and the severity, with the management of acute changes from baseline being most clinically important. Acute hypoxemia is common in patients presenting with acute onset respiratory failure, and the treatment of hypoxemia with supplemental oxygen may be of greatest immediate concern. Establishing an airway, if necessary; providing adequate oxygen; and providing ventilatory support (mechanical ventilation or noninvasive ventilation) as indicated are the mainstays of acute management and stabilization of the patient with a severe acute or acute-on-chronic respiratory acidosis. In parallel, the underlying cause of the respiratory acidosis must be treated promptly and appropriately.

Oxygen therapy should be administered cautiously to patients with chronic hypercapnia who are breathing spontaneously because the primary driver of respiratory effort may be hypoxemia rather than
hypercapnia. Supplemental oxygen may lead to a decrease in respiratory drive and a worsening of the respiratory acidosis. Careful monitoring after administering supplemental oxygen is necessary.

For a patient with chronic respiratory acidosis, most commonly because of chronic obstructive lung disease, who presents with acute respiratory failure requiring mechanical ventilation, it is important to target the patient’s estimated baseline Paco₂. Overventilation of a patient with this presentation resulting in essentially normalization of the Paco₂ will lead to reversal of the patient’s usual secondary metabolic alkalosis over several days. This will make it difficult to wean patients from mechanical ventilation when they are improved and physiologically ready for extubation. Patients will be unable to maintain an adequate minute ventilation and Paco₂ off the ventilator to avoid severe acidosis with their new [HCO₃⁻], resulting in rapid fatigue and respiratory failure after extubation. It may take several days of avoidable mechanical ventilation or the administration of exogenous alkali (sodium bicarbonate or oral sodium citrate) for patients to reconstitute their normal [HCO₃⁻] and permit them to be safely liberated from the ventilator, increasing the risk of complications and prolongation of their ICU stay. Attempts to keep patients close to their usual baseline blood gas results will reduce the likelihood of this iatrogenic complication, reduce time on mechanical ventilation, and potentially shorten ICU length of stay.

There are no specific drug treatments for managing a respiratory acidosis. Using several targeted drug therapies including bronchodilators, corticosteroids, antibiotics, anticoagulants, thrombolytics, opiate antagonists, and others is important in managing underlying causes of respiratory acidosis, but these have no direct effects on the acid-base disorder. Some have advocated for administering chloride replacement therapy in patients with a combined respiratory acidosis and metabolic alkalosis. The concomitant metabolic alkalosis further depresses respiratory drive, worsening the increase in Paco₂. The intravenous administration of dilute hydrochloric acid has resulted in resolution of the metabolic alkalosis and
concomitant improvement in the respiratory acidosis.\textsuperscript{58,59} Although this has been reported in the literature, it is an uncommon treatment approach in the setting of a severe respiratory acidosis.

**Respiratory Alkalosis**

Respiratory alkalosis is the least common of the acid-base disorders in critically ill patients. A persistent increase in minute ventilation leads to a reduction in Paco\textsubscript{2} and alkalemia. As with respiratory acidosis, the disorder is divided into acute and chronic respiratory alkalosis according to the clinical presentation and history. The secondary response is a reduction in SID and a resulting decline in [HCO\textsubscript{3}^{-}], with a greater quantitative response with a chronic respiratory alkalosis (see Table 1.3 and Table 1.4). The most common causes of respiratory alkalosis in critically ill patients are pain, anxiety, fever, and hypoxemia.
secondary to pneumonia, pulmonary edema, or pulmonary embolism. Central nervous system lesions secondary to traumatic brain injury or tumor are also potential causes of respiratory alkalosis. Salicylate overdose can stimulate respiratory drive, leading to a respiratory alkalosis, which is often associated with a concomitant elevated AG metabolic acidosis, although early in the presentation, the respiratory alkalosis may be predominant. Mild to moderate respiratory alkalosis is generally asymptomatic and does not typically require treatment; however, severe alkalosis (pH greater than 7.60) can be associated with light-headedness, confusion, syncope, and seizures, likely because of decreased cerebral blood flow. Patients may also be more prone to cardiac arrhythmias because of sensitization to circulating or exogenously administered catecholamines. Electrolyte abnormalities may include hypokalemia, decreased ionized calcium, and hypophosphatemia. For patients with traumatic brain injury, the reduction in cerebral blood flow associated with respiratory alkalosis may have a detrimental effect on maintaining adequate cerebral perfusion, especially in the presence of an elevated intracranial pressure.

Treatment is focused primarily on treating the underlying cause, including the administration of analgesics for pain, sedatives for anxiety, and antipyretics for fever, as appropriate. Treating the underlying cause of hypoxemia and providing supplemental oxygen can reduce minute ventilation and resolve the metabolic alkalosis. In patients with CNS-mediated increases in minute ventilation (e.g., traumatic brain injury or tumor), it is often difficult to lower minute ventilation because patients will often overbreathe the ventilator. Sedation, and in severe cases neuromuscular paralysis, may be needed to permit reductions in minute ventilation. Dead space can also be added to the ventilator circuit to increase the rebreathing of expired gases and increase Paco₂.66

Mixed Acid-Base Disorders

Mixed acid-base disorders are very common in critically ill patients
because of the combination of acute illnesses, underlying chronic diseases, and the influence of treatments that are administered. Just about any combination of respiratory and metabolic acid-base abnormalities can coexist, depending on the clinical presentation, and it is therefore imperative that a full evaluation of the acid-base status using the stepwise approach discussed earlier be completed. It is not uncommon to have a patient with sepsis who has had significant vomiting or nasogastric tube losses who has been resuscitated with normal saline and administered vasopressors to support unstable hemodynamics. That combination of clinical events could lead to a mixed acid-base disorder, including elevated AG metabolic acidosis secondary to sepsis and shock, metabolic alkalosis owing to the loss of upper GI secretions, and hyperchloremic metabolic acidosis secondary to large volumes of normal saline. A patient with baseline chronic obstructive lung disease and a chronic respiratory acidosis presenting with severe diarrhea, hypovolemic shock secondary to intravascular volume loss, and acute respiratory failure could potentially have an acute-on-chronic respiratory acidosis, a hyperchloremic metabolic acidosis secondary to severe diarrhea, and an elevated AG metabolic acidosis owing to shock and poor tissue perfusion. These are just two examples to show the potential for mixed disorders as a result of the complexities of the presentation of acutely ill patients admitted to the adult ICU.

**INTRAVENOUS FLUIDS AND ACID-BASE DISORDERS**

As discussed previously, the choice of intravenous fluid therapy can have an important impact on acid-base status, and recent publications have raised concerns that fluid composition may also affect patient outcome.\(^{16,17,68}\) The relative electrolyte content of the intravenous fluid compared with the patients’ plasma concentrations and volume administered may have an important impact on SID and therefore acid-base status. A solution that has a SID lower than plasma \([\text{HCO}_3^-]\) will lead to a reduction in SID and the development of a hyperchloremic acidosis, whereas solutions with a SID greater than plasma \([\text{HCO}_3^-]\)
will increase SID and lead to a metabolic alkalosis.44,45,69

As discussed previously, normal saline (0.9% sodium chloride for injection) has a SID of zero and, when administered in large volumes, will decrease plasma SID and lead to a hyperchloremic metabolic acidosis. Other intravenous fluids that are commercially available and considered more balanced electrolyte solutions are lactated Ringer solution, Plasma-Lyte (available as Plasma-Lyte 148 and Plasma-Lyte A), and Normosol-R. Lactated Ringer solution has an effective SID of 28 mEq/L as long as the patient is able to clear the 28 mEq/L of lactate in the solution. In the setting of severe liver dysfunction, lactate clearance will be significantly decreased, and lactated Ringer solution will have an effective SID closer to zero. When lactate is adequately cleared, lactated Ringer solution is not expected to contribute to the development of a metabolic acidosis. Plasma-Lyte 148, Plasma-Lyte A, and Normosol-R solutions have an effective SID of 50 mEq/L because of the metabolic clearance of acetate and gluconate after administration of the fluid. Both Plasma-Lyte solutions have the same electrolyte composition; however, Plasma-Lyte A and Normosol-R have the solution pH adjusted to 7.4. This is not clinically relevant from an acid-base perspective, and the solutions can be used interchangeably. These balanced solutions have the added advantage of being able to be administered concomitantly with blood product transfusions, whereas lactated Ringer solution cannot because of the presence of lactate, which will cause the formation of a precipitant with the calcium contained in blood products. This is particularly relevant in the operating room, where fluids and blood products are often administered concomitantly through the same intravenous access. Because the SID of the balanced solutions is 50 mEq/L, large volumes of these solutions may lead to a metabolic alkalosis; therefore, careful monitoring is indicated.

Two extemporaneously prepared fluids that provide additional flexibility relative to managing acid-base status are ½ normal saline (0.45% sodium chloride for injection) with sodium bicarbonate 75 mEq/L and sterile water for injection with sodium bicarbonate 150 mEq/L. Both of these solutions are isotonic and have SIDs of 75 mEq/L.
and 150 mEq/L, respectively. It is recognized that it may not be practical in many clinical settings to routinely use these options, given the need to extemporaneously prepare the solutions. Combining these five intravenous fluid choices, the bedside ICU clinician has options that range from a SID of 0 mEq/L to 150 mEq/L, allowing an ability to carefully adjust and manage acid-base status during continued intravenous fluid resuscitation and maintenance therapy. If we include the options of 0.1N and 0.2N hydrochloric acid infusions, the range of SIDs available will be as low as −200 mEq/L.

Several recent clinical trials have shown that the choice of intravenous fluid in the resuscitation of critically ill patients does affect acid-base status. Chua et al. reported the results of a retrospective comparison of patients resuscitated with Plasma-Lyte 148 or normal saline in the treatment of DKA. Patients who received Plasma-Lyte had quicker resolution of their metabolic acidosis, less risk of developing hyperchloremia, improved urine output, and a higher mean arterial blood pressure at 2–4 hours than did the group of patients who received normal saline. Young and coworkers conducted a randomized, double-blind trial comparing Plasma-Lyte A and normal saline for resuscitation during the first 24 hours after traumatic injury. All patients required blood transfusions and were intubated, and most went to surgery within 60 minutes of arrival. Patients receiving Plasma-Lyte A had a greater resolution of the baseline metabolic acidosis and a lower plasma [Cl−]. The volume of fluids administered and the urine output in the first 24 hours were not different, and there was no difference in mortality. These studies are consistent with the expected effect of a balanced electrolyte solution on acid-base status compared with normal saline; however, they were inadequately powered to show an effect on important clinical outcomes.

A large observational study of patients undergoing major open abdominal surgery compared outcomes for patients receiving normal saline (n = 30,994) or a balanced electrolyte solution (n = 926) on the day of surgery. The saline-treated group had a greater mortality rate (5.6% vs. 2.9%; p<0.001) and more major complications (33.7% vs. 23%; p<0.001). In a propensity-matched sample, patients receiving the
balanced electrolyte solution had significantly fewer complications, including postoperative infections, renal failure requiring dialysis, blood transfusions, and electrolyte disturbances. Patients receiving normal saline were also more likely to experience a metabolic acidosis requiring intervention. Yunos and colleagues reported the results of a prospective, open-label, sequential study comparing patients who were treated with chloride-rich intravenous fluids (normal saline, 4% succinylated gelatin solution, or 4% albumin solution) during the control period (n = 760) and a chloride-restrictive fluid (Hartman solution, Plasma-Lyte 148, or chloride-poor 20% albumin) during the intervention period (n = 773). Patients receiving chloride-rich fluids had a significantly greater risk of experiencing acute kidney injury and requiring renal replacement therapy. There were no differences in hospital mortality, hospital or ICU length of stay, or need for renal replacement therapy after discharge. These two studies suggest that resuscitation using chloride-rich intravenous fluids not only increases the risk of hyperchloremic metabolic acidosis, but also contributes to negative outcomes, including renal injury and the need for renal replacement therapy. A double-blind, randomized, crossover study of healthy volunteers receiving a 2-L volume of normal saline or Plasma-Lyte 148 over 1 hour showed that saline was associated with a significantly greater reduction in renal artery blood flow velocity and renal cortical tissue perfusion. This experimental trial provides biologic plausibility that chloride-rich fluids adversely affect renal perfusion and consequently renal function in critically ill patients. However, it has been cautioned that well-controlled, adequately powered studies are needed to confirm or refute the benefits of a balanced electrolyte solution compared with normal saline. Critical care clinicians should treat resuscitation fluids like any other drug available in the ICU. The choice of fluid should be carefully considered in light of the indications, contraindications, and potential adverse effects and then reconsidered regularly according to the patient’s metabolic and clinical response.

EXAMPLE CASES
Case 1

The first case is a 57-year-old man with a history of poorly controlled type 2 diabetes, moderate obesity, peripheral vascular disease (after a left femoral-popliteal arterial bypass 2 years before admission), diabetic nephropathy (baseline SCr 1.8 mg/dL), hyperlipidemia, and hypertension. Medications before admission include glyburide, irbesartan, and atorvastatin.

He presents to the emergency department after a several-week history of a poorly healing wound on his left foot, for which he did not seek medical care. On admission, he is obtunded, hypotensive, tachycardic, and breathing rapidly and deeply. His initial blood pressure is reported as 89/43 mm Hg, his heart rate is 131 beats/minute, and his respiratory rate is 37 breaths/minute. He is diaphoretic, febrile to 39.2°C, and in clear respiratory distress. He is emergently intubated and placed on mechanical ventilation. His admission ABG was pH 7.16, Paco₂ 23 mm Hg, Pao₂ 78 mm Hg, [HCO₃⁻] 8 mEq/L, and O₂ saturation 89%. His complete blood cell count showed a white blood cell count (WBC) of 26.7 × 10³ cells/mm³ with 21% bands on differential. His serum chemistries were as follows: Na⁺ 138 mEq/L, K⁺ 3.9 mEq/L, Cl⁻ 108 mEq/L, total CO₂ 9 mEq/L, albumin 2.1 g/dL, blood glucose 479 mg/dL, SCr 6.2 mg/dL, and blood urea nitrogen (BUN) 64 mg/dL. Lactate was 5.2 mEq/L, and serum ketones were negative. He is oliguric with a urine output of less than 0.5 mL/kg/hour.

Physical examination reveals a necrotic, open, and draining left foot wound with cellulitic tissues surrounding areas of necrosis. The wound has significant surrounding crepitance, and there is concern that this represents early gangrene. There are no palpable pulses in the foot or lower leg. He is admitted with planned transfer to the surgical ICU for resuscitation, mechanical ventilation, and antibiotic therapy together with surgical evaluation. The admitting diagnosis is severe sepsis and septic shock secondary to necrotic, nonviable left foot.

Although a quick review of his laboratory data indicates that he has an elevated AG metabolic acidosis and elevated blood lactate concentration, a stepwise approach to his acid-base assessment is
needed to fully understand his status. Taking the stepwise approach, the following results are found:

1. Given his clinical presentation, the following would be expected:
   - Severe sepsis/shock – elevated AG metabolic acidosis
   - Acute-on-chronic renal injury – elevated AG metabolic acidosis

2. pH = 7.16, consistent with acidemia

3. The $[\text{HCO}_3^-] = 8 \text{ mEq/L}$ and $\text{Paco}_2 = 23 \text{ mm Hg}$ are consistent with a principal metabolic acidosis (see Table 1.3).

4. Not applicable. The principal disorder is not respiratory.

5. The secondary disorder equation for a principal metabolic acidosis is:

\[
\text{Paco}_a \text{CO}_2 = 1.5 \times [\text{HCO}_3^-] + 8 \pm 2
\]

\[
\text{Paco}_2 = 1.5 \times 8 \text{ mEq/L} + 8 \pm 2 = 20 \pm 2 \text{ mEq/L}
\]

His actual $\text{Paco}_2$ is 23 mm Hg, which, within the limits of these estimates, is consistent with meeting his expected new normal $\text{Paco}_2$ for this degree of metabolic acidosis.

6. The equation for calculating the ACAG is (assuming a normal albumin of 4 g/dL):

\[
\text{ACAG} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) + 2.5([\text{normal albumin}] - [\text{observed albumin}])
\]

\[
\text{ACAG} = (138 + 3.9) - (108 + 8) + 2.5(4 - 2.1) = 30.7 \text{ mEq/L}
\]

7. The delta ratio equation is:
\[ \text{Delta Ratio} = \frac{ACAG - \text{normal AG}}{\text{Normal} [HCO_3^-] - \text{Measured} [HCO_3^-]} \]
\[ = \frac{(ACAG - 12)}{(24 - [HCO_3^-])} \]

\[ \text{Delta Ratio} = \frac{30.7 - 12}{24 - 08} = \frac{18.7}{16} = 1.2 \]

8. Not required

The final assessment from taking the stepwise approach is that the patient presented with an elevated AG metabolic acidosis with an appropriate secondary response and no evidence of a concomitant acid-base disorder. This is consistent with the clinical presentation. Of interest, the ALCAG can also be calculated to evaluate for other unmeasured anions contributing to the metabolic acidosis:

\[ ALCAG = ACAG - [\text{lactate}] = 30.7 - 5.2 = 25.5 \text{ mEq/L} \]

This indicates that there are unmeasured anions making a significant contribution to the metabolic acidosis in addition to lactate. This could be inorganic anions accumulating because of acute-on-chronic renal injury or other products of tissue necrosis and ischemia.

The treatment considerations in this case should be primarily focused on treating the septic shock with fluid resuscitation and vasopressors, if indicated; providing broad-spectrum antibiotics; and, as soon as stabilized, providing definitive surgical management of the source of infection. Fluid resuscitation should include either a bicarbonate-containing solution (e.g., ½ normal saline with 75 mEq/L of NaHCO₃) or a balanced electrolyte solution (e.g., Plasma-Lyte A). An initial bolus of 50–100 mEq of NaHCO₃ could be considered given his baseline pH of 7.16; however, giving prompt fluid resuscitation with an alkaline solution and providing mechanical ventilation will likely make this unnecessary. Targets are a central venous pressure of 8–12 mm
Hg (if available) and a mean arterial pressure greater than 60–65 mm Hg.

His initial management in the emergency department consisted of fluid resuscitation with normal saline (about 70 mL/kg total), and, because of persistently low mean arterial pressure, an infusion of epinephrine was initiated and titrated to an infusion rate of 0.4 mcg/kg/hour. His mean arterial pressure is currently 65–68 mm Hg, and his urine output has improved to greater than 0.5 mL/kg/hour. Broad-spectrum antibiotics were initiated early. About 4 hours after presentation, laboratory testing was repeated, with ABG results of pH 7.31, Paco₂ 29 mm Hg, Pao₂ 98 mm Hg, HCO₃⁻ 14 mEq/L, and O₂ saturation 96%. Lactate is improved but still elevated at 4.4 mEq/L. Serum chemistry results are Na⁺ 141 mEq/L, K⁺ 3.5 mEq/L, and Cl⁻ 116 mEq/L.

Using the stepwise approach, the results now show a principal metabolic acidosis and partial resolution of the elevated AG (ACAG is 19.3 mEq/L); however, the delta ratio is now 0.7 mEq/L, consistent with a concomitant normal AG, hyperchloremic metabolic acidosis presumably because of the large volume of normal saline administered. Despite the improvement in hemodynamics and urine output suggesting successful resuscitation, the lactate concentration remains elevated. Failure to clear lactate may be associated with a higher risk of mortality. In this case, the persistently elevated lactate concentration may be a result of using epinephrine vasopressor therapy, which may increase aerobic glycolysis and contribute to a type B lactic acidosis. At this point, the patient’s fluid therapy should be changed to a bicarbonate-containing or balanced solution as initially recommended, and his epinephrine infusion should be transitioned to norepinephrine, which is less likely to increase lactate production. The stepwise approach showed a change in the acid-base status in this case secondary to iatrogenic factors that may not have been readily evident without a complete workup of the acid-base status. Fully understanding the acid-base disorder affected the therapeutic decisions for this patient.
Case 2

The second case is a 19-year-old man who was previously healthy. He was a non-restrained driver involved in a rollover motor vehicle accident and has sustained a significant traumatic brain injury (Glasgow Coma Scale score 8) together with many orthopedic injuries, including a significant crush injury to his right lower extremity with clinical evidence of compartment syndrome. The trauma team has opened the fascia of the anterior and posterior compartments of the right lower extremity. He was resuscitated with intravenous normal saline and is intubated, mechanically ventilated, and presently in the trauma ICU. His laboratory values include Na\(^+\) 134 mEq/L, K\(^+\) 4.6 mEq/L, Cl\(^-\) 114 mEq/L, and albumin 1.4 g/dL. His most recent ABG is pH 7.36, Paco\(_2\) 22 mm Hg, Pao\(_2\) 97 mm Hg, HCO\(_3^-\) 12 mEq/L, and O\(_2\) saturation 99%. He has evidence of rhabdomyolysis secondary to the crush injury with a creatine kinase of 12,540 U/L, SCr 1.4 mg/dL, and BUN 28 mg/dL, and he is relatively oliguric (urine output 25–50 mL/hour).

Using the stepwise approach to his acid-base status provides the following results:

1. The clinical presentation would suggest the following:
   - Crush injury/rhabdomyolysis – elevated AG metabolic acidosis
   - Resuscitation with normal saline – hyperchloremic metabolic acidosis
   - Traumatic brain injury – respiratory alkalosis

2. pH = 7.36 is on the low end of the normal range.

3. [HCO\(_3^-\)] = 12 mEq/L and Paco\(_2\) = 22 mm Hg are consistent with a principal metabolic acidosis.

4. Not applicable

5. 

\[
Paco_2 = 1.5 \times [HCO_3^-] + 8 \pm 2
\]

\[
Paco_2 = 1.5 \times 12 \text{ mEq/L} + 8 \pm 2 = 26 \pm 2 \text{ mEq/L}
\]
6. Calculation of the ACAG:

\[
\text{ACAG} = ([\text{Na}^+] + [K^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) + 2.5([\text{normal albumin}] - [\text{observed albumin}])
\]

\[
\text{ACAG} = (134 + 4.6) - (114 + 12) + 2.5(4 - 1.4) = 19.1 \text{ mEq/L}
\]

7. Calculation of the delta ratio:

\[
\text{Delta Ratio} = \frac{\text{ACAG} - \text{normal AG}}{\text{Normal} [\text{HCO}_3^-] - \text{Measured} [\text{HCO}_3^-]}
\]

\[
= \frac{(\text{ACAG} - 12)}{(24 - [\text{HCO}_3^-])}
\]

\[
\text{Delta Ratio} = \frac{19.1 - 12}{24 - 12} = \frac{7.1}{12} = 0.6
\]

8. Not applicable

The stepwise approach shows that the patient has a combined elevated AG metabolic acidosis, respiratory alkalosis, and normal AG, hyperchloremic metabolic acidosis. These are all consistent with the clinical presentation, but this would not be readily evident without using a stepwise approach because a quick review of the laboratory results would likely conclude that the patient had a compensated elevated AG metabolic acidosis secondary to his crush injury and rhabdomyolysis.

Although there is no urgency to treat the acid-base disorder, changing his current intravenous fluid therapy to a balanced electrolyte solution or a bicarbonate-containing intravenous solution is important to prevent worsening hyperchloremic metabolic acidosis. Performing a baseline and follow-up lactate concentration is recommended to monitor the effectiveness of treating the compartment syndrome, and the patient’s acid-base status should be closely monitored, given that resolution of the AG and non-AG metabolic acidoses may lead to a
significant alkalemia because of the concomitant respiratory alkalosis. Changes to minute ventilation should be tried to increase Paco₂; however, sedation may be needed if the patient has a persistent respiratory alkalosis despite ventilator setting changes. Additional dead space in the ventilator circuit could also be considered. A full understanding of this combined acid-base disorder permits the development of a comprehensive therapeutic plan relative to his acid-base status.

Case 3

The patient described in case 1 with the necrotic left foot and severe sepsis was stabilized and underwent left below-the-knee amputation. Early in the management of his severe sepsis, he required considerable fluid resuscitation to achieve and maintain goal hemodynamics, and his weight increased from a baseline 92 kg to 123 kg with evidence of significant peripheral edema. By day 5 of his hospital stay, he was hemodynamically stable and off all vasopressors, his SCr had decreased to 2.1 mg/dL, and he was making 30–50 mL/hour of urine. Because of a concern that the peripheral edema would impair his ability to wean from mechanical ventilation and increase his risk of skin breakdown, he was initiated on a continuous furosemide infusion at a rate of 4 mg/hour, resulting in a brisk diuresis. During the next 48 hours, he remained hemodynamically stable and had diuresed almost 16 L of fluid. His peripheral edema was markedly improved, and he was making progress weaning from mechanical ventilation. Morning laboratory results included an ABG with pH 7.52, Paco₂ 46 mm Hg, Pao₂ 73 mm Hg, HCO₃⁻ 36 mEq/L, and O₂ saturation 92%. Serum chemistry results were Na⁺ 138 mEq/L, K⁺ 3.8 mEq/L, Cl⁻ 98 mEq/L, total CO₂ 37 mEq/L, lactate 0.9 mEq/L, and albumin 2.1 g/dL. Given his stable hemodynamics, unchanged renal function tests, and continued need to remove excess fluids, the ICU team would like to continue diuresis with the goal of potentially shortening his time on mechanical ventilation and ICU length of stay.

The stepwise approach to his acid-base status results in the
following analysis:

1. The clinical story since resolution of his initial severe sepsis is consistent with:
   - Loop diuretic use – metabolic alkalosis
   - Chronic renal disease – elevated AG metabolic acidosis, or possible normal AG metabolic acidosis
2. pH = 7.49 indicating alkalemia
3. \([\text{HCO}_3^-] = 36 \text{ mEq/L and Paco}_2 = 46 \text{ mm Hg}\) are consistent with a principal metabolic alkalosis.
4. Not indicated
5. The equation for the secondary change because of metabolic alkalosis is (see Table 1.4):
   - The actual Paco\(_2\) is 46 mm Hg, indicating that the secondary response is appropriate for his current [\text{HCO}_3^-].
6. His ACAG is not elevated at 11.6 mEq/L.
7. Not indicated
8. Not indicated

The stepwise process shows that the patient has a metabolic alkalosis with an appropriate secondary respiratory response. Discontinuing the loop diuretic and administering normal saline adequate to replete the Cl\(^-\) deficit would be an effective treatment for this chloride-responsive metabolic alkalosis; however, that would be counterproductive to the goals of the ICU team to remove fluid and resolve his peripheral edema. The initial recommended treatment option is to administer acetazolamide (500 mg intravenously for one dose) to increase urinary Na\(^+\) excretion and decrease SID. In our experience, this is adequate to lower \([\text{HCO}_3^-]\) with improvement in the metabolic alkalosis despite continuing diuresis; however, the effect is usually short-lived (24–36 hours). If, after that intervention, there is a continued need to diurese the patient, the chloride deficit can be replaced using an infusion of dilute 0.1N hydrochloric acid intravenous
solution. Although the dose can be based on a calculation of the Cl\(^-\) deficit, we recommend starting at 40 mL/hour in an adult patient and adjusting the infusion according to the response, using the safety precautions discussed previously. A hydrochloric acid infusion can also be used as an initial treatment option in lieu of acetazolamide.

Case 4

The fourth case is a 76-year-old woman admitted to the hospital with a small bowel obstruction and 3 days of vomiting. Her medical history is significant for chronic obstructive lung disease (home O\(_2\)-dependent), hypertension, and hypercholesterolemia. She had a nasogastric tube inserted and placed to wall suction and was draining about 1 L per day. Her abdominal examination was considered benign, and she was admitted to the medical service for conservative management. On the second day of her hospitalization, she developed a temperature to 39.5°C, her WBC was elevated to 28.2 \(\times\) 10\(^3\) cells/mm\(^3\), and she developed hypotension and tachycardia. She was tachypneic, diaphoretic, and clearly in respiratory distress. Just before intubation, her ABG results were pH 7.23, Paco\(_2\) 36 mm Hg, Pao\(_2\) 74 mm Hg, HCO\(_3\)^- 15 mEq/L, and O\(_2\) saturation 90%. Her chemistries showed the following: Na\(^+\) 141 mEq/L, K\(^+\) 3.9 mEq/L, Cl\(^-\) 105 mEq/L, and albumin 1.9 g/dL. Lactate was 5.8 mEq/L. She was initiated on broad-spectrum antibiotics, and resuscitative efforts were initiated. Surgery was consulted for evaluation and potential surgical management.

From the perspective of her acid-base status, the stepwise approach provides the following analysis:

1. Given the clinical presentation, the following would be expected:
   - Chronic obstructive lung disease – chronic respiratory acidosis
   - Respiratory failure – acute-on-chronic respiratory acidosis
   - Sepsis/shock – elevated AG metabolic acidosis
   - Vomiting/nasogastric tube losses – chloride-responsive metabolic alkalosis
2. pH = 7.23, indicating acidemia

3. $[\text{HCO}_3^-] = 15 \text{ mEq/L}$ and $\text{Paco}_2 = 36 \text{ mm Hg}$ are consistent with a principal metabolic acidosis.

4. Given the principal disorder, this step could be skipped; however, given the history, it is likely this patient has a chronic respiratory acidosis. Her admission laboratory results included $[\text{HCO}_3^-] = 38 \text{ mEq/L}$. Although that could represent a metabolic alkalosis secondary to her 3-day history of vomiting, it is also consistent with a chronic respiratory acidosis. Her acute respiratory failure may result in an acute-on-chronic respiratory acidosis that may confuse the interpretation of her secondary response to the metabolic acidosis.

5. 

$$\text{Paco}_2 = 1.5 \times [\text{HCO}_3^-] + 8 \pm 2$$

$$\text{Paco}_2 = 1.5 \times 15 \text{ mEq/L} + 8 \pm 2 = 30.5 \pm 2 \text{ mEq/L}$$

The actual $\text{Paco}_2$ is 36 mm Hg, consistent with a concomitant respiratory acidosis.

6. 

$$\text{ACAG} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) + 2.5([\text{normal albumin}] - [\text{observed albumin}])$$

$$\text{ACAG} = (141 + 3.9) - (108 + 15) + 2.5(4 - 1.9) = 33.2 \text{ mEq/L}$$

8. Not indicated

This patient has a triple acid-base disorder with concomitant elevated AG metabolic acidosis, respiratory acidosis, and metabolic alkalosis. This is consistent with the clinical presentation, and the metabolic alkalosis component is likely a combination of upper GI secretory losses and underlying chronic respiratory acidosis.

As with case 1, treatment of this patient must be focused on managing her severe sepsis, including fluid resuscitation with a balanced solution (e.g., Plasma-Lyte A), vasopressors as indicated according to response to fluids, broad-spectrum antibiotics, ventilator support, and appropriate surgical source control. Her presumed chronic respiratory acidosis will need to be considered in her treatment. Although reducing Paco$_2$ during mechanical ventilation may have some short-term benefit in the acute management of her metabolic acidosis, the goal longer term will need to be achieving a Paco$_2$ closer to her suspected baseline and administering bicarbonate-containing intravenous fluids to keep her [HCO$_3^-$] close to her admission value. This will prepare this patient for the best chance of successfully weaning from mechanical ventilation when her condition improves. The metabolic alkalosis from upper nasogastric tube losses should improve with fluid resuscitation.

\[
\text{Delta Ratio} = \frac{ACAG - \text{normal AG}}{\text{Normal } [HCO_3^-] - \text{Measured } [HCO_3^-]}
\]

\[
= \frac{(ACAG - 12)}{(24 - [HCO_3^-])}
\]

\[
\text{Delta Ratio} = \frac{33.2 - 12}{24 - 15} = \frac{21.2}{9} = 2.4
\]

CONCLUSION

Acid-base disorders are common in critically ill patients, are often complex mixed disorders, and are associated with significant morbidity
and mortality. A thorough stepwise approach to evaluating the acid-base status of an ICU patient is required to fully understand all contributors to the status of the patient and best inform the therapeutic approach and necessary monitoring plan. Although we acknowledge the practicality of taking a traditional bicarbonate-based approach to the diagnostic evaluation of acid-base status, this model is inadequate to explain the underlying physiology and therefore the most appropriate approach to treating the patient. The physiochemical model with its emphasis on the independent parameters that affect acid-base status, namely $\text{Paco}_2$, SID, and $A_{\text{TOT}}$, provides a clearer understanding of the causes and subsequent treatment approaches to complex acid-base disturbances. With advances in technology and automation and integrated electronic medical records, a bedside diagnostic approach using the Figge-Stewart model may be readily available in all ICUs and could become the routine diagnostic approach to acid-base disorders; however, this will require changes to how we teach students and trainees relative to the diagnosis and management of acid-base disturbances.

Chapter 2  Fluid Therapy in the Critically Ill Patient

Brian L. Erstad, Pharm.D., FCCP, BCPS

LEARNING OBJECTIVES

1. Discriminate between the concepts of osmolality, osmolarity, and tonicity.
2. Compute the osmolarity of monovalent ions and albumin in an intravenous solution.
3. Explain the upper and lower limits of osmolarity for fluids or medications being administered by peripheral veins.
4. Describe the concept of a balanced intravenous crystalloid solution.
5. Compare the efficacy and adverse effect profiles of commercially available intravenous colloid solutions.
6. Characterize the properties of albumin that distinguish it from other colloids.
7. Summarize the findings of the large randomized controlled trials that have involved intravenous crystalloid and colloid comparisons.
8. Describe treatment considerations that are unique to the following subsets of critically ill patients requiring fluid resuscitation: trauma, severe sepsis/septic shock, and burns.
9. Explain the concerns of overly aggressive intravenous fluid administration for resuscitating patients in shock.
10. Appraise the benefits and limitations of invasive monitoring
techniques that have been used for patients undergoing resuscitation.

11. Summarize the appropriate uses of colloids and crystalloids for resuscitating critically ill patients.

**INTRODUCTION**

Discussions of fluid therapy in critically ill patients often devolve into a debate of colloid versus crystalloid administration. This is an oversimplification as well as an inappropriately restrictive dialogue of the important considerations associated with choosing and administering fluids to critically ill patients. The primary purpose of this chapter is to discuss important considerations when using intravenous crystalloid and colloid solutions for acute resuscitation. This first major section of this chapter will cover the general properties of these intravenous solutions, beginning with a discussion of the concepts of osmolality, osmolarity, and tonicity and whether central line access is indicated for fluid administration. A historical perspective for each of the more common intravenous fluids will be provided that leads into a discussion of more recent investigations. Albumin will be a major focus of the colloid discussion because it was the first colloid to receive widespread use in the clinical setting, has been the subject of much
research, and is the standard of comparison for other colloids. The next two sections will review the most important and influential studies involving crystalloids and colloids in critically ill patients and major subsets of critically ill patients. This will be followed by sections on dosing and assessment issues related to fluid administration, with an abbreviated discussion of maintenance fluids post-resuscitation. The final section is devoted to general recommendations for the use of intravenous crystalloids and colloids in critically ill patients.

OVERVIEW OF CRYSTALLOIDS AND COLLOIDS USED IN CRITICALLY ILL PATIENTS

General Considerations
Disruptions in normal gastrointestinal and circulatory homeostasis in critically ill patients commonly necessitate the administration of intravenous fluid solutions to maintain oxygen delivery and associated cellular processes. From a macrocirculation standpoint, oxygen delivery is a function of three parameters: cardiac output, hemoglobin, and oxygen content (more specifically oxygen saturation). Under normal circulatory conditions, oxygen delivery greatly exceeds the amount of oxygen uptake needed by tissues (i.e., delivery-independent), but during more severe forms of shock, oxygen consumption by tissues is directly linked to oxygen delivery (i.e., delivery-dependent). Therefore, in patients undergoing resuscitation for shock, intravenous crystalloid and colloid solutions are given to increase plasma volume and optimize cardiac output. Regardless of the specific type of shock (e.g., hypovolemic, distributive, obstructive, cardiogenic), adequate intravascular expansion with fluids must be ensured. This includes patients with septic shock, who usually must receive at least 20 mL/kg of fluids to be classified as having refractory hypotension and be enrolled in randomized controlled trials (RCTs). Of the patients with septic shock who have met the criteria for study entry in large RCTs, around 25%–35% respond to intravenous fluids in conjunction with infection control and do not require additional vasoactive support. From a regional circulation or microcirculation standpoint, maintenance and
monitoring of circulatory homeostasis is more complicated and depends on the type and severity of shock. For example, in the early hyperdynamic phase of sepsis, cardiac output typically increases to above-normal values in patients without preexisting cardiac disease, but local or regional shunting prevents selected tissues from benefiting from this enhanced global oxygen delivery. Together with the increased recognition of the importance of microcirculatory changes associated with states of impaired perfusion and the implications for fluid administration, there has been an increased appreciation of the pharmacologic actions of intravenous resuscitation fluids beyond simple plasma expansion. There is now a better understanding of how the electrolyte composition of intravenous fluids influences acid-base status (see Chapter 1 for a more in-depth discussion), how particular electrolytes such as chloride may have adverse effects beyond acid-base disturbances, and how certain colloidal products (particularly albumin) have physicochemical properties that may improve or worsen patient outcomes, depending on the specific clinical scenario.

Oncotic Pressure, Osmolality, Osmolarity, and Tonicity

From 1994 to 1998, the U.S. Food and Drug Administration (FDA) received 10 reports of patients who developed hemolysis after being administered an inappropriately diluted albumin solution. The details surrounding the hospital course of two of these patients (one who died) were discussed in an issue of Morbidity and Mortality Weekly Report published in 1999.¹ The hemolytic events occurred when a shortage of 5% albumin led hospital pharmacists to prepare a 5% albumin solution by diluting 25% albumin with sterile water for injection. This resulted in an albumin solution that was about one-fifth the osmolarity of normal plasma. In five of the reported cases, the pharmacists had used a reference handbook on injectable drugs for instructions on the albumin dilution process, but the version of the text being used contained erroneous information. Instead of using sterile water for injection for the dilution procedure, the pharmacists should have used a fluid such as normal saline or 5% dextrose in water to dilute the 25% albumin. These were preventable adverse events that would not have occurred
had the involved pharmacists had an appreciation of osmolarity. The purpose of this section of the chapter is to provide definitions for the terms oncotic pressure, osmolality, osmolarity, and tonicity. Examples will be used to show how osmolarity is calculated for common intravenous fluids, and practical recommendations will be provided to help the clinician determine when low- and high-osmolarity intravenous solutions should be given by central versus peripheral intravenous lines.

Albumin is a plasma protein responsible for around 75% of oncotic pressure, but less than 1% of total osmotic pressure, in the blood. For this discussion, the term colloid osmotic pressure as an alternative to oncotic pressure will not be used because the former term causes confusion with respect to the measurement or estimation of osmotic pressure in the blood. Under physiological conditions, albumin does not readily pass through the semipermeable capillary membrane, so it is one of the main factors affecting transcapillary fluid movement through its oncotic activity. It is possible to measure oncotic activity with an oncometer, but this testing is not routinely available in the clinical setting. Because it is the number, not the size, of particles that determines osmolality/osmolarity, albumin exerts only a small amount of the total osmotic pressure in blood compared with other solutes like electrolytes. Osmolality is the measure of solute expressed in milliosmoles per kilogram (mOsm/kg) of solvent. The denominator of the units is expressed in kilograms because osmolality is reported by an osmometer in a clinical laboratory using methods such as freezing point depression (the gold standard) or vapor pressure and is not altered by changes in pressure or temperature. Osmolarity is the measure of solute expressed in milliosmoles per liter (mOsm/L) of solvent. It is usually estimated from calculations made in serum laboratory indices (e.g., 2 × serum sodium + BUN/2.8 + glucose/18). From an intravenous medication or fluid administration standpoint, differences in the definitions of osmolality or osmolarity based on the denominator of each have little clinical importance because blood has a relatively constant temperature and pressure. For the remainder of this discussion, osmole or osmolarity will be used for simplicity.

Although osmolarity is a property irrespective of a membrane, osmolarity is referenced to fluid movement across the red blood cell
membrane when referring to intravenous fluid administration. A hypo-osmolar solution will tend to move water into red blood cells, and a hyperosmolar solution will tend to move water out of red blood cells. The word *tend* is italicized because some osmoles such as urea equilibrate across cell membranes and cause no net fluid movement in or out of cells, although a high BUN would elevate blood osmolality as measured by a clinical laboratory. The fluid shifts associated with osmolarity differences are considered to occur during or within 1–2 hours after intravenous medication or fluid infusion. The calculated osmolarity of monovalent electrolytes in solution are straightforward if the usual assumption of complete dissociation is made. Using the example of an intravenous sodium chloride solution in which a milliequivalent per liter (mEq/L) equals a milliosmole per liter (mOsm/L), a 0.45% saline solution has 77 mEq/L (i.e., 77 mOsm/L) of sodium and 77 mEq/L (i.e., 77 mOsm/L) of chloride for a total osmolarity of 154 mOsm/L. This hypo-osmolar solution represents the lower limit of osmolarity usually tolerated by peripheral veins compared with the reference standard of normal blood osmolarity of around 300 mOsm/L. Normal saline with an osmolarity of 308 mOsm/L is considered iso-osmolar.

Tonicity is often called “effective osmolality” because it equals the sum of concentrations of effective solutes (not ineffective solutes such as urea) that exert osmotic activity after an intravenous solution has been administered and subsequently distributed into body fluid compartments, resulting in a state of final equilibrium. In the body, tonicity is referenced with respect to the cell membrane, so isotonic refers to no net fluid shift between the intracellular and the extracellular compartments. Hypotonic refers to expansion of intracellular fluid, and hypertonic refers to contraction or shrinkage of intracellular fluid, each with respect to the extracellular fluid compartment; as with osmolarity, extremes of tonicity cause cell damage. Taken together, osmolarity and tonicity can be used to describe common intravenous solutions. For example, normal saline is iso-osmolar and isotonic. A 5% dextrose solution is relatively iso-osmolar (252 mOsm/L) but hypotonic (two-thirds of the volume after final distribution is contained by the intracellular compartment and one-third by the extracellular
compartment). A 25% dextrose solution (assuming adequate endogenous or exogenous insulin) would be hyperosmolar but hypotonic. However, a 25% dextrose solution administered to a patient with insulin deficiency likely would be considered both hyperosmolar and hyper-tonic, because the dextrose would not cross the cell membrane to be oxidized as it would under normal conditions.

Of note, ex vivo experiments of potential red blood cell lysis is a unique situation from a terminology perspective. In such experiments, red blood cells are added to various solutions to see whether the integrity of the red cell membrane is maintained. If hemolysis occurs, a solution is considered hypotonic or hypertonic, depending on the mechanism of cell damage.

Osmolarity is a function of the number of particles in solution and is independent of size or weight of particles. If 8 albumin molecules (MW 67,000) and 16 glucose molecules (MW 180.16) were separated by a semipermeable membrane in sterile water for injection, the water would move toward the glucose molecules because osmolarity is independent of size and weight. Thus, although the molecular weight and size of albumin are much greater compared with ions such as sodium or chloride, commercially available albumin solutions would have unacceptably low osmolarity if the solutions did not contain other additives with osmotic activity (usually sodium and chloride). See Appendix 2.1 for an example of osmolarity calculations involving albumin.

Peripheral vs. Central Line Administration

Osmolarity is one of the main factors that determines whether fluids (or medications) should be given by intravenous peripheral or central line administration. The toxicity associated with hypo- or hyperosmolar solutions is a function of both the rate and the volume of the infusate administered and the duration of administration in addition to the peripheral or central route of access. Most studies that have evaluated potential osmolarity concerns have used continuous intravenous infusions of solutions for administration periods of at least 10 minutes. About 150 mOsm/L is generally considered the lower limit of osmolarity
when infusing products through peripheral veins such as those in the antecubital fossa. Even a 0.45% sodium chloride solution with 154 mOsm/L will cause irritation and burning when infused through peripheral veins in some patients. In addition to causing a patient pain, administering hypo-osmolar solutions by peripheral veins may cause vein destruction, local tissue irritation caused by extravasation, and loss of access for fluid or medication administration. Although the latter local problems are unlikely to occur when central veins are used for infusing hypo-osmolar solutions, hemolysis caused by hypo-osmolarity is a concern regardless of central or peripheral access. Deaths caused by hemolysis and renal failure have been reported with the inadvertent administration of sterile water for injection (0 mOsm/L) in the intensive care unit (ICU) setting.²

The upper end of the acceptable range of osmolarity is controversial and often based on hemolysis in animal models, which may not be directly applicable to humans. For example, dog red blood cells are deficient in ATPase, and their permeability to positively charged cations is influenced by cell volume, so they are more fragile than human red blood cells.³ In one ex vivo study of dog and human red blood cells, no hemolysis occurred when cells were mixed with sodium chloride in dextran solutions to yield osmolarity values of up to 600 mOsm/L (based on detection of free hemoglobin), but increasing hemolysis was noted over a range of 900–2400 mOsm/L.⁴ These values of 600 mOsm/L and 900 mOsm/L are the upper limits of osmolarity often used in nursing and pharmacy guidelines or protocols, but another aspect of this study provided more information on osmolarity concerns. In the other part of the study, severely bled dogs were resuscitated with hyperosmolar solutions administered over 10 minutes by peripheral vein or into the right atrium. As defined by plasma-free hemoglobin concentrations, hemolysis was more than 2-fold greater when two hyperosmolar solutions (1.5 mL/kg of 25% sodium chloride in 24% dextran [around 8600 mOsm/L] or 2.5 mL/kg of 15% sodium chloride in 14.4% dextran [around 5200 mOsm/L]) were administered by peripheral vein versus the right atrium. No hemolysis was noted when 5 mL/kg of a 7.5% sodium chloride in a 6% dextran solution (around
2600 mOsm/L) was administered by peripheral vein. The findings of this and related earlier studies served as the basis for the upper limits of osmolarity used in subsequent studies involving the use of hypertonic saline solutions in trauma patients.

Much of the human data relating osmolarity to peripheral vein phlebitis have been derived from studies involving parenteral nutrition solutions, although the methods of assessing phlebitis in these studies varied. In one study, phlebitis occurred in 100% of patients when osmolarity was greater than 600 mOsm/L in those given either parenteral nutrition or crystalloid solutions. In this same study, adding heparin (1000 units/L) to various solutions increased the risk of phlebitis over non–heparin-containing solutions (p<0.05). Although this finding seems counterintuitive given the known antiphlebitic actions of heparin, it appeared to be attributable to the increased osmolarity of solutions containing heparin (634 ± 153 vs. 477 ± 100 mOsm/L, p<0.001). Other studies have been unable to confirm an association between the osmolarity of parenteral nutrition solutions and the rate of phlebitis. For example, one study found no difference in tolerance using radioactive fibrinogen to assess thrombophlebitis when solutions of 280–1100 mOsm/L were administered. In another study, parenteral nutrition solutions above 600 mOsm/L (630–983 mOsm/L) were well tolerated, and fat emulsion did not influence the rate or degree of phlebitis. Similarly, there was no difference in phlebitis between the parenteral nutrition solutions of 1200 mOsm/L and 1700 mOsm/L when administered by peripheral lines. The apparent lack of correlation between osmolarity and phlebitis when the solutions are less than around 1000 mOsm/L is at least partly explained by the results of one study involving peripheral vein tolerance of parenteral nutrition solutions of varying macronutrients, osmolarity, volume, and rate of administration. In this study, there was poor correlation between rates of phlebitis, as determined by two observers and by factors such as macronutrient composition or osmolarity. But there was a high correlation (r=0.95) between phlebitis and osmolarity rate (osmolality in mOsm/L times infusion rate in L/hour). The rate of phlebitis after 48 hours was 4%–27% with an osmolarity rate of 84–99 mOsm/hour. The
time to onset of phlebitis was not related to the osmolarity rate. Apart from parenteral nutrition solutions, the most studied high-osmolarity fluid given by peripheral vein in clinical trials has been hypertonic sodium chloride. Hyper-tonic sodium chloride of up to around 250 mL of a 7.5% solution (2566 mOsm/L) has been remarkably free of apparent complications such as phlebitis or hemolysis when given by one-time or intermittent bolus administration.\textsuperscript{10} chloride solutions in patients, not human volunteers, was published in 1989. Patients with penetrating trauma in a prehospital setting were randomized to receive a single 250-mL bolus of either an isotonic crystalloid solution or a 7.5% sodium chloride in 6% dextran 70 solution, each administered by a 14-gauge peripheral catheter. As with the 25 patients in the isotonic crystalloid group, none of the 23 patients randomized to the hypertonic sodium chloride group developed obvious infusion-related complications.\textsuperscript{11} In a publication the following year, the potential risks of 7.5% sodium chloride with (n=23) or without (n=32) dextran were compared with lactated Ringer’s (n=51) using data collected from two randomized double-blind investigations. There were no significant differences in measured osmolalities between the hypertonic sodium chloride and the lactated Ringer’s groups at any time point. Nor was there any evidence of central pontine myelinolysis in the 52 patients who died, including 20 patients with serum osmolality measurements (obtained within 15 minutes in 75% of patients) greater than 350 mOsm/kg.\textsuperscript{12} In 14 patients with repeated osmolality measurements, values were less than 350 mOsm/kg within 4–8 hours. There were no significant differences in serum sodium concentrations (a surrogate indicator of osmolality) between hypertonic sodium chloride (with or without dextran) and lactated Ringer’s groups. Severe hypernatremia, as defined by a sodium of 160 mEq/L or greater, occurred in 1 of 32 patients administered hypertonic sodium chloride without dextran and in 1 of 24 patients receiving lactated Ringer’s (this patient received 7.5% sodium bicarbonate as part of CPR 3–5 minutes before measurement) in one of the randomized trials and in 1 of 23 patients administered hyper-tonic sodium chloride plus dextran and 0 of 24 patients receiving lactated Ringer’s in the other
randomized trial. Although the findings from this evaluation of hypertonic sodium chloride solutions must be interpreted in light of the relatively small numbers of patients and potential confounders (e.g., elevated ethanol concentrations), the study is important because it has been cited as a proof-of-safety concept for subsequent investigations, including the two landmark Resuscitation Outcomes Consortium (ROC) trials. The ROC trials did not detail serum osmolality values related to hypertonic sodium chloride administration, but they did report on serum sodium values that can be used to estimate osmolarity. In the first ROC trial, sodium concentrations greater than 160 mEq/L necessitating intervention occurred in 2.2% of patients receiving hyper-tonic sodium chloride, 1% of patients receiving hypertonic sodium chloride plus dextran, and 1.4% of patients receiving normal saline (no significant difference). In the second trial, sodium concentrations greater than 160 mEq/L necessitating intervention occurred in 4.2% of patients receiving hypertonic sodium chloride, 2.9% of patients receiving hypertonic sodium chloride plus dextran, and 2.3% of patients receiving normal saline (no significant difference). Other studies involving single doses of hypertonic sodium chloride have found sodium and chloride concentrations to be about 8–10 mEq/L higher than the values in isotonic crystalloid control groups, but usually less than 155 mEq/L for sodium and less than 120 mEq/L for chloride with no mention of phlebitis. Although hypertonic sodium chloride causes acute increases in serum sodium concentrations that correspond with increases in serum osmolality measurements, correlation with other outcomes such as intracranial pressure is poor.

Many of the studies looking at osmolarity issues of peripheral veins are difficult to interpret because they did not control for pH while investigating osmolarity issues. Intravenous solutions need to have a lower pH limit of about 6.5 to exclude acidity as a cause of phlebitis, based on histopathologic evaluations of infused solutions in rabbit ear veins. A pH of 9 seems to be the upper limit of alkaline tolerability according to indirect evidence from infusions of medications such as THAM (tris-hydroxymethyl aminomethane). Even if pH is controlled, osmolarity tolerance is a function of other patient-specific factors such
as blood flow, diameter, and integrity of the vein being infused and duration of fluid administration. Histopathologic evaluations after infusions into rabbit ear veins with controlled pH (i.e., greater than 6.5) show that in vessels with poor flow, tolerance decreases as osmolarity increases from 550 mOsm/kg to 820 mOsm/kg; furthermore, tolerance with the 820-mOsm/kg solution is better with a higher infusion rate (i.e., 15 mL/kg/hour vs. 5–10 mL/kg/hour) when given as a 120-mL/kg total dose.\textsuperscript{20} As mentioned earlier, the increased tolerance of higher-osmolarity solutions when given as one-time injections at a more rapid rate of administration over a relatively short period may explain how hypertonic sodium chloride solutions with osmolarity values above 2000 mOsm/L were apparently tolerated in studies of trauma patients.\textsuperscript{21}

In light of these data, a conservative upper limit of osmolarity for fluids given as continuous infusions into peripheral veins would be 600 mOsm/L. An upper limit of 900 mOsm/L would be more practical for the macronutrient components of total nutrient admixture solutions (dextrose, protein, and fat) given by the peripheral intravenous route, particularly when fluid overload is a concern; however, it should be realized that adding micronutrients is likely to bring the final osmolarity closer to 1000–1100 mOsm/L, which may not be tolerated by patients with fragile vessels, including older adult patients. Similarly, although one-time doses of hypertonic sodium chloride solutions with osmolarities up to 2600 mOsm/L have been given by the peripheral route in clinical studies, a solution osmolarity of 900 mOsm/L is a conservative upper value that should limit the risk of hemolysis when solutions are administered by the peripheral route on a one-time or intermittent basis.\textsuperscript{22} Although central veins can tolerate continuous infusions of high-osmolarity solutions because of their larger vessel size and more rapid blood flow rate, hemolysis is still a concern, especially as the infused solutions exceed 2600 mOsm/L. Finally, it is of note that osmolarity is not the only reason for giving intravenous solutions through central veins. Other factors include solutions with extremes of pH or potential for tissue damage if extravasation occurs (e.g., vasopressors).
Sodium Chloride Solutions

Although one of the first electrolyte solutions resembling the sodium, chloride, and bicarbonate content of blood was described in 1832,\textsuperscript{23} it was not until 1896 that Hartog Hamburger was given credit for developing a 0.9% sodium chloride solution that was similar in osmolarity to human and animal blood.\textsuperscript{24} When “normal saline” became synonymous with 0.9% sodium chloride and common parlance in the scientific community is unclear; furthermore, the terminology is misleading because the fluid does not resemble the amounts or composition of electrolytes in the intravascular compartment or any other fluid compartment of the body.\textsuperscript{25}

When given rapidly in large amounts, “normal” saline will cause a hyperchloremic metabolic acidosis compared with other solutions more reflective of usual blood electrolyte composition.\textsuperscript{26} Such pH changes, as occur with other intravenous solutions, assume a system that is open to carbon dioxide (i.e., an in vivo system). In an in vitro closed system, the regulators of acid-base status (i.e., carbon dioxide, weak acids, and the strong ion difference) are all diluted to the same degree by common intravenous solutions, resulting in no net pH change regardless of the particular solution being administered.\textsuperscript{27} In addition to the metabolic acidosis associated with the high chloride content of normal saline–containing solutions, there is increasing evidence that excess chloride ion is associated with acute kidney injury and possibly increased mortality. The mechanism by which chloride might cause acute kidney injury is not clear, although studies of healthy volunteers have found better renal cortical perfusion with more balanced chloride intravenous solutions. Among other functions, the renal cortex is important for urine concentration, filtration, and metabolic waste regulation. In general, studies investigating the association between chloride and the various clinical outcomes fall into two general categories: studies involving intravenous solutions with more balanced (i.e., closer to normal serum chloride concentrations) versus high chloride concentrations and studies evaluating normal versus high serum chloride concentrations. Early studies investigating this association appeared in the surgery literature, but more recently, a
similar concern has been raised in critically ill patients. In one prospective open-label trial, crystalloid and colloid fluids containing at least 128 mmol/L of chloride in a historical control period were compared with crystalloid and colloid fluids containing less than around 110 mmol/L of chloride (which includes the 20% albumin product manufactured in Australia where the study was conducted) during an intervention period in the year after high chloride-containing fluids had been phased out.\textsuperscript{28} For the primary end points, the increase in creatinine and incidence of acute kidney injury as defined by RIFLE criteria (injury and failure class) were significantly greater (\(p=0.03\) and \(p<0.001\), respectively) in the historical control (i.e., high chloride fluids) compared with the intervention period; also, the need for renal replacement therapy was greater in the historical control group (\(p=0.005\)), although there were no significant differences in mortality or length of stay. Other cohort studies involving critically ill patients have found a relationship between high chloride concentrations in serum or intravenous fluids and increased mortality. Large randomized studies are needed to confirm this association between higher chloride concentrations and adverse outcomes, but the weight of the evidence to date is clearly cause for concern and has raised questions about the use of high chloride solutions as first-line resuscitation fluids.

**Hypertonic Sodium Chloride Solutions**

In addition to the potential for rapid extracellular expansion with smaller amounts of fluid, mechanistic arguments in favor of hypertonic sodium chloride products have been made. For example, hypertonic sodium chloride solution suppresses, whereas lactated Ringer’s solution activates neutrophils in ex vivo models, and there is a concern that neutrophil activation may promote organ injury such as acute respiratory distress syndrome (ARDS).\textsuperscript{29}

Of note, there is always the potential for adverse effects with any concentrated electrolyte solution, but there are also nomenclature concerns associated with the use of hypertonic sodium chloride (or hypertonic saline) solutions. In the past, hypertonic saline was often considered synonymous with 3% sodium chloride solution. In reality,
any sodium chloride solution above isotonic saline of 0.9% is hypertonic, and commercially available solutions are available up to 23.4%. Therefore, the term hypertonic saline is at best misleading and is not sufficient to indicate the prescription of any particular product.

Other Crystalloid Solutions

Normal saline is often called unbalanced because its electrolyte composition does not resemble that of human blood. Attempts have been made to produce so-called balanced electrolyte solutions, although the term balanced implies a level of simplicity that does not exist in the clinical setting. Typically, balanced refers to congruence of the electrolyte composition of a fluid compared with that of blood in a healthy subject, although the terminology has not been standardized. This makes some sense for electrolytes like sodium and chloride that are primarily distributed into the extracellular compartment, but it makes less sense for electrolytes like potassium that are largely contained in the intracellular compartment. The issue is further complicated by electrolytes such as lactate, acetate, and gluconate that are metabolized over time to bicarbonate equivalents. Depending on the specific composition of electrolytes, the pH of blood might change as a solution is being administered because of strong ion differences and alterations in nonvolatile weak acids (e.g., albumin, phosphate). After fluid and electrolyte administration, blood pH might be further altered by weak acid metabolism, shifts or losses of albumin, or changes in carbon dioxide as might occur with mechanical ventilation. Few critically ill patients consistently have fluid and electrolyte compositions in the normal laboratory ranges for blood, so the amount and type of desired fluid depends on the specific patient. Of importance, because the term balanced has not been standardized, some researchers have considered a balanced solution primarily with respect to sodium and chloride concentrations that are less than that of normal saline (but in some cases, still higher than normal concentrations of blood). Perhaps it is more appropriate to refer to these more complex electrolyte solutions as more balanced than normal saline.
Arguably, the first solution to be studied as a more balanced alternative to normal saline was Ringer’s solution. The origin of Ringer’s solution can be traced to experiments by Sydney Ringer in the late 1800s in which he investigated the influence of various electrolytes on frog heart muscle contraction. Ringer’s solution containing potassium chloride, magnesium chloride, and calcium chloride was subsequently modified by Alexis Hartmann (i.e., Hartmann’s solution) by adding sodium lactate. Compared with normal saline, the electrolyte concentrations in Hartmann’s solution and lactated Ringer’s are more reflective of physiologic blood electrolyte composition. Of importance, there may be differences in the specific concentrations of electrolytes in lactated Ringer’s, depending on the manufacturer and country of origin. In the United States, Lactated Ringer’s Injection USP contains sodium 130 mmol/L, potassium 4 mmol/L, calcium 1.5 mmol/L, chloride 110 mmol/L, and lactate 28 mmol/L. For comparison, Hartmann’s has 0.5 mmol/L more calcium and 1 mmol/L more of the remaining electrolytes. Of note, there are commercially available electrolyte solutions with concentrations of ions that are closer to normal physiologic blood concentrations (particularly with respect to sodium and chloride) than those in lactated Ringer’s injection. For example, Plasma-Lyte A and Normosol-R each has the following additives: sodium 140 mmol/L, chloride 98 mmol/L, potassium 5 mmol/L, magnesium 1.5 mmol/L, acetate 27 mmol/L, and gluconate 23 mmol/L. In addition, in contrast to lactated Ringer’s, Plasma-Lyte A–like normal saline is compatible with blood products. There is increasing support for these more balanced fluids. For example, a position statement by the Faculty of Intensive Care Medicine, the Royal College of Anaesthesia, the Intensive Care Society, and the College of Emergency Medicine states that balanced solutions “such as Hartmann’s injection, Ringer’s lactate or Plasma-Lyte 148® may be preferred to 0.9% sodium chloride” for fluid resuscitation in all forms of hypovolemic shock, including sepsis, burns, and trauma. But as alluded to earlier, “normal” concentrations relative to blood may not be the appropriate goal for many patients, particularly in the post-resuscitation phase of hospitalization. For example, hyponatremia is common in many
hospitalized patients, but it is far more likely to be caused by fluid overload than by sodium deficiency. In such patients, excess sodium may worsen the fluid overload state, and the appropriate intervention is to reduce fluid provision.

Except under extreme metabolic derangements (e.g., hepatic failure), the amount of lactate in lactated Ringer’s injection (United States Pharmacopeia products) maintains a blood pH of around 7.4 soon after administration through its metabolism into bicarbonate in a 1:1 ratio. This is because an administered crystalloid solution such as a lactated Ringer’s injection must have a strong ion difference of around 24 mEq/L to maintain normal blood pH. Box 2.1 lists the common adverse effects of three of the more commonly used intravenous crystalloid solutions.

### Box 2.1. Adverse Effects of Crystalloid Solutions

**Normal saline**
- Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
- Hyperchloremic metabolic acidosis (has 154 mEq/L [154 mmol/L] of chloride)
- Hyponatremia (has 154 mEq/L [154 mmol/L] of sodium)

**Lactated Ringer’s**
- Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)
- Hyponatremia (has 130 mEq/L [130 mmol/L] of sodium)
- Aggravation of preexisting hyperkalemia (has 4 mEq/L [4 mmol/L] of potassium)

**Hypertonic sodium chloride**
- Primarily extensions of pharmacologic actions (e.g., fluid
Hypernatremia (has 513 mEq/L [513 mmol/L] of sodium)

Hyperchloremia (has 513 mEq/L [513 mmol/L] of chloride)

Colloids
Four major classes of colloids have been used for fluid resuscitation in critically ill patients: gelatins, dextran, hydroxyethyl starches, and albumin. Gelatins are not available in the United States and have not been investigated in any of the larger randomized blinded investigations sufficiently powered for a mortality end point. Furthermore, data from observational trials suggest an increased risk of acute kidney injury with gelatin products, so there is little justification for their use in the clinical setting. Similarly, although dextran products are commercially available, their use has been largely supplanted by other colloids, and they have not been investigated in adequately powered studies, with one exception. The exception is research investigations involving trauma patients (particularly those with head injuries) when dextrans have been used in combination with hypertonic sodium chloride products in an attempt to extend the duration of the plasma expansion of the crystalloid solutions. This use of dextrans is primarily based on their molecular mass (e.g., 6% dextran 70 has a relative molecular mass of 70,000) because the endothelial glycocalyx is impermeable to molecules greater than around 70,000 Da. Of importance, in contrast to albumin, which is a monodisperse molecule with a molecular mass of 67,000 Da, other colloid products are composed of polydisperse molecules, so their mass is relative (i.e., a range of molecular masses). Molecular mass has implications not only for intravascular retention, but also for potential adverse effects such as kidney injury. Furthermore, although often not considered in trial designs, colloid
products such as the dextrans and starches have anticoagulation effects beyond those attributable to the hemodilution associated with the administration of any crystalloid or colloid plasma expander that does not contain red blood cells. Because of their infrequent use in the clinical setting (at least in the United States), neither the gelatins nor the dextrans will be discussed in more detail in this chapter.

Box 2.2. Adverse Effects of Colloid Solutions

**Albumin**

- Primarily extensions of pharmacologic actions (e.g., fluid overload; dilutional coagulopathy)
- Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (e.g., parenteral nutrition)
- Anaphylactoid/anaphylactic reactions (life-threatening reactions rare; higher in patients with immunoglobulin A deficiency)
- Infectious complications (all reported cases have been associated with improper handling by manufacturer or institution; no reported cases of human immunodeficiency virus or hepatitis transmission)
- Interactions with medications and nutrients (clinical significance varies)
- Metal loading, particularly aluminum (long-term administration in patients with renal failure)
- Negative inotropic effect; reductions in ionized calcium concentrations (not well documented)
- Pyrogenic reactions (not well documented)
- Renal dysfunction with hyperoncotic albumin

**Hydroxyethyl starch**
Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)

Bleeding; not recommended in critically ill patients or in patients with bleeding conditions such as subarachnoid hemorrhage

Macroamylase formation may cause an elevation in blood amylase that leads to an inaccurate diagnosis of pancreatitis

Anaphylactoid/anaphylactic reactions

Pruritus (particularly when large amounts are given; may take months to resolve)

Renal dysfunction; not recommended in critically ill patients, patients at risk of renal dysfunction, or patients with preexisting renal dysfunction

**Dextrans**

Primarily extensions of pharmacologic actions (e.g., fluid overload, dilutional coagulopathy)

Anaphylactoid/anaphylactic reactions (increased incidence of anaphylaxis with increased molecular weight)

Bleeding (sometimes used for anticoagulant activity, so not recommended for patients with or at risk of severe bleeding)

Renal dysfunction

As with the previous discussion of intravenous crystalloid products, each of the following sections covering albumin and hydroxyethyl starch products will begin with a historical perspective to give a context to the current controversies regarding their use. Because albumin has several
properties with theoretical clinical benefits beyond plasma expansion, these properties will be reviewed. Box 2.2 lists the adverse effects of most concern with albumin, starch, and dextran products.

**Albumin**

Although some of the first experiments of the oncotic actions of albumin were conducted by Lazarus-Barlow and Starling in the late 1890s,\(^{35,36}\) clinical investigations of albumin did not begin until albumin was separated from plasma through a fractionation process developed by the protein chemist Edwin Cohn of Harvard Medical School at the request of the armed forces in 1940 in preparation for World War II. Bovine-derived albumin was the initial focus of plasma substitution efforts, but serum sickness reactions associated with the product further shifted efforts to studies with human plasma and albumin. The bovine albumin program officially ended near the end of 1943. A 25% human serum albumin product was developed that met the armed services request for a product that was not only safe and effective, but also concentrated, stable, and easy to transport and administer. Cohn was instrumental in developing the procedures for the commercial production of albumin. The small amount of albumin that had been produced by 1941 was given to casualties of Pearl Harbor and deemed effective, so in January 1942, the National Research Council recommended that albumin be used by all the armed forces.\(^ {37}\) In conjunction with its use on the battlefield, albumin continued to be studied for its clinical effects in normal volunteers (mainly medical students) and patients with shock.\(^ {38-40}\)

Many of the physicochemical properties (e.g., molecular weight, oncotic activity), clinical benefits (e.g., ease of administration, efficacy for shock), and risks (e.g., venous and pulmonary edema) of albumin were elucidated soon after the fractionation process was developed.\(^ {41-43}\) Part of the research on albumin involved ways to improve its stability and clinical efficacy through the addition of various additives, including sodium chloride. Consideration was even given to albumin in dry powder form with a diluent that contained glucose. Sodium chloride concentrations as high as 0.3 molar were considered
and tested as dispersion mediums for albumin, but eventually, a “salt-poor” 0.15 molar sodium chloride concentration (i.e., 0.9%) was used. By 1950 (the year in which albumin was included in the United States Pharmacopeia), research on albumin had provided several findings that were subsequently confirmed in later investigations with more advanced techniques. Examples include:

- Concentrated 25% albumin draws fluid from the extravascular to the intravascular space, so concomitant isotonic fluid administration is needed to optimize plasma expansion and prevent potential adverse effects in patients with preexisting extravascular depletion.

- The major adverse effect of albumin is fluid overload resulting from excessive administration; other serious adverse reactions are rare.

- Albumin begins to leak into the extravascular space soon after administration, particularly in patients with increased vascular permeability (e.g., cirrhosis, nephrosis, burns).

- Albumin is not a substitute for whole blood in patients with hemorrhagic shock.

- Denaturation of albumin occurs with production and storage.

By the earlier 1970s, there was a widespread perception that the clinical use of albumin had increased substantially. There were concerns that some of the widespread use of albumin might be inappropriate, especially in light of the cost of the product. This led to a workshop on albumin that was sponsored by the Division of Blood and Blood Products, the Bureau of Biologics, the FDA, and the Division of Blood Diseases and Resources, National Heart and Lung Institute, NIH. In preparation for the workshop, a survey of 1.4% of hospitals registered by the American Hospital Association showed that 25% albumin was most prescribed on a unit basis (18,845 units of 50 mL), followed by plasma protein fraction (9956 units of 250 mL) and 5% albumin (1650 of 250 mL). The 2-day workshop convened sessions on the history of albumin, the biochemistry and physiology of albumin,
the physiology of body fluid compartments, and the clinical uses and safety of albumin. In addition to the publication of the proceedings by the Division of Blood Diseases and the Resources of the National Heart and Lung Institute, a summary of the findings of the proceedings was published in two parts in the Journal of the American Medical Association (JAMA) in 1977.\textsuperscript{46,47} The uses for albumin defined as “appropriate” were shock, adult respiratory distress syndrome, and cardiopulmonary bypass. “Occasional use” was deemed appropriate for acute liver failure, red blood cell suspension media, ascites, after surgery, acute nephrosis, and renal dialysis. The only uses considered “unjustified” were undernutrition, chronic nephrosis, and chronic cirrhosis. Of note, not a single RCT involving albumin had been published when the workshop took place. The recommendations were mainly based on mechanistic and experimental models, and observational studies. Although it was clear that albumin had several biological functions, the importance of these functions was not always clear. For example, by the early 1970s, the condition of analbuminemia was recognized in which patients lived well into adulthood, despite a lack of detectable albumin concentrations in the blood. Although it was difficult to try to limit albumin use in the absence of randomized trials and when general indications such as shock were considered appropriate, many clinicians developed institutional guidelines and protocols for albumin use using the results of the conference proceedings. One could argue that the publication of the JAMA paper was the beginning of the so-called colloid versus crystalloid debate that still rages. No other attempts were made to define the appropriate uses of albumin on a widespread basis until the early 1990s, when the University Hospital Consortium (now known as the University HealthSystem Consortium) compiled recommendations for the appropriate uses of albumin and other nonprotein colloids, published in 1995.\textsuperscript{48} These recommendations were based largely on evidence from RCTs that had been conducted since the first trials in the mid to late 1970s. Using the University HealthSystem Consortium recommendations to define appropriate albumin use, an observational study was conducted at 15 academic medical centers in the United
States. Almost two-thirds of albumin use in this study was found to be inappropriate, with an associated institutional cost of about $125,000. By the late 1990s, when recombinant albumin was successfully produced (but not economically viable by large-scale production), the crystalloid-colloid debate was reignited by several factors, including increasing use of albumin substitutes for cost containment, increased use of systematic reviews and/or meta-analyses to evaluate crystalloid-colloid efficacy and safety in critically ill patients, and the publication of RCTs of sufficient sample size to assess mortality as an end point in critically ill patients receiving crystalloids and colloids.

Properties of Albumin
The plasma expansion by albumin was previously thought to be caused by its oncotic actions in a simple physiological model in which transcapillary fluid transport was determined by intravascular and interstitial oncotic and hydrostatic forces in conjunction with membrane permeability coefficients for protein and water. Fluid transport across the endothelium is now known to be a function of the oncotic and hydrostatic forces of blood and the subglyceal (not the interstitial) space. The oncotic pressure of the subglyceal space is determined by albumin. When the glycocalyx is damaged, as may occur during critical illness, fluid leaks into the interstitial space. This leak, together with the increased rate of catabolism of albumin, accounts for the hypoalbuminemia that commonly occurs in critically ill patients. Other colloids such as hydroxyethyl starch may help maintain glycocalyx integrity, but not to the same degree as albumin.

Albumin has a variety of other properties not shared by other colloid or crystalloid solutions (see Box 2.3). These properties have been used to support mechanistic explanations for the clinical benefits of exogenous albumin administration, even though most comparative studies with other colloids or crystalloids have found no advantage to albumin on clinically relevant patient outcomes. Some have argued that the apparent lack of benefit of albumin over other fluid products is that it has not been studied using the appropriate methodology in specific subsets of critically ill patients. There are other explanations as well.
One alternative explanation is that other proteins take over the functions of albumin during states of albumin deficiency, and another explanation is that exogenous albumin does not have the same physicochemical properties of endogenous albumin. Each of these alternative explanations will be discussed.

**Box 2.3. Properties of Albumin Beyond Plasma Expansion and Glycocalyx Integrity**

- Suppresses effects of cytokines (TNF neutrophil burst)
- Anticoagulant actions possibly caused by nitric oxide inactivation
- No neutrophil activation and decreased neutrophil sequestration in lung
- Transport/binding to endogenous substances (bilirubin, steroids, fatty acids, nitric oxide) and drugs
- Scavenger for reactive oxygen species
- Source of amino acids

*TNF = tumor necrosis factor.*

Albumin does provide a source of amino acids, but it is a poor source of essential amino acids, and albumin deficiency is unlikely to be a rate-limiting step in protein synthesis except in cases of prolonged malnutrition. Albumin is considered an antioxidant, but depending on other clinical conditions such as iron overload, it may have no significant antioxidant activity and may even have pro-oxidant effects. Albumin serves as a reversible binding protein for several endogenous and exogenous ligands, but the clinical importance of this binding has not been well established. For those who argue for albumin’s beneficial mechanistic actions, perhaps the most cogent counterargument is based on cases of analbuminemia in which patients lived well into
adulthood without obvious consequences. Obviously, the functions of albumin in such cases were taken over by other proteins, so the important questions from a clinical standpoint are whether this compensatory process occurs in the setting of critical illness and, if so, how long it takes other proteins to perform the more important functions of albumin.

Endogenous albumin has both positive and negative charges on different parts of the molecule, although there is an overall net negative charge. This accounts not only for the binding of endogenous substances such as bilirubin, but also for some of the medications commonly used in critically ill patients such as midazolam, phenytoin, and valproate. The binding properties may be impaired during the manufacturing and storage of albumin products. Denatured albumin has decreased oncotic activity and may dispose patients to sensitivity reactions. For these reasons, commercially available albumin products are not biologically similar to endogenous albumin.

**Hydroxyethyl Starch**

The first hydroxyethyl starch solution licensed in the United States was Hespan (1972) formulated in normal saline, followed by Hextend (1999) formulated in Ringer’s lactate, and finally, Voluven (2007) formulated in normal saline. Hespan approval was based on small randomized comparisons with albumin in a variety of surgical and critically ill patient populations, whereas the Hextend and Voluven approval studies used other starch products such as Hespan as the control. All of these products had upper dose limits in the labeling (20 mL/kg for Hespan and Hextend, 50 mL/kg for Voluven). Bleeding concerns beyond dilutional effects were noted in early studies of Hespan and Hextend, but renal adverse effects did not become a significant concern until larger head-to-head comparisons with other colloids or crystalloids began to appear in the literature in the early part of this century. Overarching conclusions about evaluations of starch efficacy, as well as adverse effect concerns such as bleeding, have been complicated by the variety of products that have been studied in the United States and other countries. In contrast to albumin, starch products are not
monodisperse. Each starch product has a range of molecular weights, a degree of hydroxyethyl starch molar substitution on glucose subunits, and a degree of hydroxyethyl starch molar substitution on glucose subunits typically expressed as the ratio of hydroxyethyl groups at C2 versus C6. For example, Voluven is described as 6% hydroxyethyl starch 130/0.4, where 6% indicates the weight, 130 is the molar substitution, and 0.4 is the ratio of hydroxyethyl groups. It was previously thought that higher molecular weight and degree of starch substitution were the primary causes of the adverse effects of the hydroxyethyl starch products because of prolonged retention in reticuloendothelial tissues and alterations in coagulation. Therefore, more recent promotional materials and research has focused on products like Voluven.

### CRYSTALLOID AND COLLOID STUDIES IN CRITICALLY ILL PATIENTS
Potential differences in the electrolyte composition of intravenous solutions that may influence the efficacy and safety end points in clinical studies are an issue not only for crystalloid products but also for colloid products. This point needs to be considered as the following results of important crystalloid and colloid trials are discussed. Table 2.1 lists the electrolyte compositions of the crystalloids and colloids administered in some of the larger RCTs involving critically ill patients. It is currently unknown how these electrolyte differences may have influenced the results of these trials, but it should serve as a cautionary note in the design of future clinical trials.

In 1998, a systematic review conducted by the respected Cochrane group found a 6% excess mortality with albumin compared with isotonic crystalloid solutions. The authors of the analysis recommended that albumin not be used in critically ill patients outside the confines of RCTs. This publication led to a series of pro-con albumin letters to the editor of the journal, with some pointing out the various flaws of the systematic review and others recommending that albumin use be discontinued because of the findings of the review. The Cochrane analysis prompted the FDA to issue a “Dear Doctor” letter in August 1998 that urged discretion in the use of albumin and recommended that clinicians be aware of current guidelines; the specific guideline referenced was the 1995 publication by the University HealthSystem Consortium. The next year, in 1999, a well-respected group of Canadian critical care researchers published a systematic review that found no difference in clinically relevant end points between iso-tonic crystalloid solutions and colloids such as albumin for fluid resuscitation, with one exception. Lower mortality was noted in trauma patients who received crystalloid solutions (relative risk [RR] 0.39; 95% CI, 0.17–0.89). However, the authors of the systematic review noted that methodological limitations precluded high-level evidence-based recommendations and called for more randomized trials. Many other systematic reviews and meta-analyses comparing crystalloids and colloids were published within a few years of the Canadian systematic review, most of which had similar findings—no important differences in clinically relevant end points with the notable exception of trauma
subgroups, which had worse outcomes with albumin.

In 2004, the results of a randomized study were published that compared 4% albumin with normal saline for fluid resuscitation of critically ill patients. This trial, known as SAFE, was a landmark investigation not only for its size (n=6997 patients), but also for the rigor of methodology. There were no significant differences between the albumin and saline groups for the primary end point (all-cause death at 28 days) or any of the secondary end points (duration of mechanical ventilation, length of stay, or days of renal replacement therapy). However, there was a trend toward reduced mortality with albumin in patients with severe sepsis (RR 0.87; 95% CI, 0.74–1.02), and consistent with previous meta-analyses, there was a trend toward increased mortality in patients with trauma (RR 1.36; 95% CI, 0.99–1.86). In May 2005, the FDA issued a follow-up “Dear Health Care Providers” letter stating that the SAFE study had resolved the safety concerns related to albumin raised by the 1998 Cochrane systematic review.

In 2012, the CHEST study was published in which 7000 patients admitted to ICUs with a need for fluid resuscitation were randomized in a blinded manner to receive a 6% hydroxyethyl starch (130/0.4) in normal saline or normal saline. The study was modeled after the SAFE study—both had mixed medical and surgical ICU patients, and both used a pragmatic design with interventions apart from study fluids left to the discretion of the treating physicians. This type of design necessitates the large patient enrollment in both the CHEST and the SAFE trials but allows for increased generalizability of the findings. There was no significant difference in the primary end point of 90-day mortality between the starch and the saline solutions (RR 1.06; 95% CI, 0.96–1.18), but the starch solution was associated with more overall adverse effects (5.3% vs. 2.8%, p<0.001). Furthermore, there was increased acute kidney injury (34.6% vs. 38.0%, p=0.005) and increased need for renal replacement therapy (RR 1.21; 95% CI, 1.00–1.45) in patients receiving the starch solution.

Most RCTs involving crystalloid-colloid comparisons in critically ill patients have used one crystalloid solution and one colloid solution,
usually in specific subsets of patients, to limit heterogeneity and sample size. An exception to this was the CRISTAL trial published in 2013.\textsuperscript{59} This multicenter trial randomized critically ill patients in an open-label fashion to receive colloids (gelatins, dextrans, starches, and albumin products not limited by type or concentration of colloid) or crystalloids (normal saline, hypertonic sodium chloride, and Ringer’s lactate) for fluid maintenance; patients were stratified by trauma, sepsis, or shock without sepsis or trauma. No difference was found for the primary end point of 28-day mortality between the colloid group and the crystalloid group (RR 0.96; 95% CI, 0.88–1.04). However, at 90 days, mortality was reduced in the colloid group (RR 0.92; 95% CI, 0.86–0.99). Although a few other secondary end points had significant findings in favor of colloids, most other comparisons stratified by type of specific fluid or shock revealed no significant differences. It is very difficult to draw conclusions from this study, given the many potential confounders and statistical concerns with the results that were mentioned in letters to the editor by leading researchers in fluid resuscitation. Although the 2857 patients evaluated in this study seems like a large number, consider that the SAFE trial had 6997 patients, and only two fluids were compared.

**CRYSTALLOID AND COLLOID STUDIES IN SUBSETS OF CRITICALLY ILL PATIENTS**

**Trauma**

In a post hoc follow-up trial of SAFE, 460 patients with traumatic brain injury and a Glasgow Coma Scale (GCS) score of 13 or less from the original SAFE investigation were followed for 24 months.\textsuperscript{60} Mortality was higher in the albumin group than in the saline group (RR 1.63; 95% CI, 1.17–2.26), particularly in patients with more severe injury, as defined by a GCS score of 3–8 (RR 1.88; 95% CI, 1.31–2.70). So, although albumin appears to be safe in a general ICU population, saline is recommended for resuscitating patients with traumatic brain injury.

Hypertonic sodium chloride products have been studied as
resuscitation fluids for trauma, and particularly for traumatic brain injury, for decades. In May 2006, enrollment began in two randomized blinded studies conducted under the auspices of ROC, a research network with studies that include evaluations of prehospital resuscitation interventions. One of the studies investigated the efficacy and safety of prehospital administration of hypertonic sodium chloride solutions for shock caused by traumatic hemorrhage, and a parallel study investigated these solutions and end points specifically for patients with traumatic brain injury. The fluids under study were single 250-mL boluses of 7.5% sodium chloride in 6% dextran, 7.5% sodium chloride, or 0.9% isotonic saline. This dose of hypertonic sodium chloride solution was chosen because of its frequent use and safety in previous trials. Enrollment in the shock trial was suspended early (n=853) when the study monitoring board found no significant difference (p=0.91) between groups for the primary outcome of 28-day mortality. Higher mortality was associated with hypertonic sodium chloride administration in a subgroup of patients not undergoing transfusion in the first 24 hours (p<0.01). Enrollment was also terminated early (n=1331) in the second study involving patients with traumatic brain injury when no significant difference (p=0.67) was found in the primary end point of 6-month neurologic outcome (based on the Extended Glasgow Outcome Scale) between the hypertonic solution and the isotonic sodium chloride solution. Furthermore, there was no significant difference between groups for 28-day survival (p=0.88). In both trials, there were few statistically significant differences for a wide range of other outcome and adverse effect measures. Although the hypertonic sodium chloride groups had more sodium concentrations above the normal range, there were similar small numbers of patients in each group (less than 2.5% in the groups in the shock trial with numbers too small to estimate significance and less than 5% in each group in the brain injury trial with a p=0.25) with sodium concentrations greater than 160 mmol/L requiring intervention.

**Severe Sepsis and Septic Shock**
Patients with severe sepsis was one of the predefined subgroups of
the SAFE study.\textsuperscript{61} Although the unadjusted risk of death with albumin was lower and trended toward statistical significance, the risk of death with albumin after adjustment for other dependent variables was significantly lower (odds ratio [OR] 0.71; 95% CI, 0.52–0.97). There were no significant differences between the albumin group and the saline group for safety outcomes such as need for renal replacement therapy. In contrast to the SAFE trial, which used a 4% albumin product with relatively standard resuscitation end points, a subsequent large (n=1818) multicenter trial (ALBIOS) involving patients with severe sepsis or septic shock used 20% albumin targeted to achieve a serum albumin concentration of at least 30 g/L.\textsuperscript{62} Patients randomized to both the albumin and the no-albumin groups received crystalloids for fluid replacement. Although patients in the albumin group had higher mean arterial pressure (MAP) values (p=0.03) and lower net fluid balance (p<0.001), there were no significant differences in 28-day or 90-day mortality or any secondary outcome measures. There was a significant difference in favor of albumin in a subset of patients with septic shock (43.6% with albumin vs. 49.9% with crystalloid, p=0.03), but this finding should be considered hypothesis generating, given that this was a post hoc rather than a pre-specified subgroup analysis. A systematic review that included the ALBIOS trial, as well as another multicenter trial involving 20% albumin that was unpublished at the time (Early Albumin Resuscitation in Septic Shock or EARSS), found no difference in the primary end point of 28-day mortality or any secondary end points, including 90-day mortality, regardless of the degree of sepsis severity or whether serum albumin concentration was changed.\textsuperscript{63}

There is a concern that unbalanced high chloride solutions such as normal saline are more likely than balanced solutions to cause acute kidney injury. This is a potential confounding factor in randomized trials and systematic reviews comparing colloids with crystalloids in patients with sepsis when balanced and unbalanced (e.g., normal saline) solutions are combined to form a crystalloid group. In one systematic review of patients with sepsis that had separate balanced and unbalanced crystalloid groups, the balanced crystalloid group had lower mortality than the saline or starch product groups.\textsuperscript{64} It is worth
noting that this systematic review used a complicated, non-standard meta-analytic methodology, and there was significant trial heterogeneity with low confidence in most of the findings. Furthermore, the albumin arm of the analysis also showed lower mortality than the saline or starch solution arms, but the implications of this finding are hindered by the use of low and high chloride-containing albumin and starch products.

The concerns with hydroxyethyl starch solutions in patients with sepsis are not limited to products with high chloride concentrations. Large randomized studies have shown safety issues with high and low chloride-containing starch solutions in patients with sepsis. One of the first large investigations to raise concerns with starch products was known as the VISEP trial.\(^5\)\(^4\) In the fluid resuscitation part of this \(2 \times 2\) factorial trial, a lower-molecular-weight starch (i.e., 200/0.5 pentastarch) formulated in a normal saline solution was compared with Ringer’s lactate. At 90 days, there was a trend toward increased mortality in the starch group compared with the Ringer’s lactate group (\(p=0.09\)), as well as an increased rate of acute renal failure (34.9% vs. 22.8%, \(p=0.002\)) and need for renal replacement therapy (\(p=0.001\)). In another multicenter randomized blinded study known as the 6S trial, 6% hydroxyethyl starch 130/0.4 in Ringer’s acetate (118 mEq/L chloride, 24 mEq/L acetate) was compared with Ringer’s acetate, each in a dose of 33 mL/kg/day, for resuscitating 804 patients with severe sepsis.\(^5\)\(^5\) Despite the use of a low-molecular-weight hydroxyethyl starch solution that was more balanced with respect to chloride concentration, there was increased 90-day mortality (RR 1.17; 95% CI, 1.01–1.36), an increased need for renal replacement therapy (RR 1.35; 95% CI, 1.01–1.80), and a trend toward increased bleeding (RR 1.52; 95% CI, 0.94–2.48) in the starch group. In light of these findings, the FDA has required hydroxyethyl starch product information to contain a black box warning on the increased mortality and renal injury requiring renal replacement therapy associated with these solutions.

**Burns**
There is surprisingly little evidence to support the use of albumin in patients with burns, despite research of its efficacy and safety that dates back to the 1970s. The few randomized studies conducted have been inadequately powered to investigate clinically meaningful end points, even though albumin or fresh frozen plasma is often part of resuscitation protocols. Guidelines by the American Burn Association recognize the limitations of the literature in this area and begin by recognizing that data are insufficient to support a treatment standard. In the guidelines, colloid therapy such as albumin is simply listed as an option that may reduce fluid requirements if given at least 12–24 hours after injury. Nevertheless, the theoretical benefit of albumin is appealing, particularly in patients with large burns who require substantial fluid administration. In one investigation with a before-after design (n=98 before, n=61 after), 5% albumin was used to replace lactated Ringer’s solution at 12 hours post-burn when estimated fluid requirements at 12 hours suggested that a patient would need at least 6 mL/kg per percent burn at 24 hours. Ventilator-associated pneumonia (p<0.01), number of days on the ventilator (p<0.05), and mortality (p<0.01) were lower in the after (i.e., albumin) phase of the study. In addition to the possibility of a type I statistical error, given the substantial difference in mortality between groups, the results are confounded by the use of a historical control (with use of colloids per physician discretion after 24 hours in the before phase) and the implementation of a protocol that included standardization beyond the addition of albumin in the after phase. Larger randomized trials are needed to confirm the findings of this study.

Miscellaneous

Albumin in particular has been studied for several specific disease states and in conjunction with a variety of surgical and nonsurgical procedures in critically ill patients. Apart from fluid resuscitation studies that typically have involved isotonic crystalloid versus relatively iso-oncotic colloids such as albumin 4% or 5%, the hyperoncotic albumin products (20% and 25%) have been studied for conditions in which interstitial to intravascular fluid movement is thought to be desirable and
conditions that would appear to benefit from the properties of albumin beyond plasma expansion. However, the trial by Sort et al. involving patients with spontaneous bacterial peritonitis is the only adequately powered RCT to date to find a significant reduction in unadjusted mortality with hyperoncotic albumin (20%) compared with no albumin with mortality being a primary end point of the study.\textsuperscript{67} With patients in both groups receiving cefotaxime, the mortality rates with and without albumin were 41% and 22% (p=0.03), respectively, and the rates of renal impairment were 33% and 10% (p=0.002), respectively. Other areas of investigation of albumin, particularly hyperoncotic albumin, include nephrosis, cirrhosis, cardiopulmonary bypass surgery, and the adult respiratory distress syndrome. There is no high-level evidence to support the routine use of albumin in these areas. An in-depth discussion of each of these uses is beyond the scope of this chapter, but Table 2.2 provides an example of some of the more common purported indications for albumin, together with possible dosing regimens and evidence to support each use.\textsuperscript{68–74} This protocol adapted from the author’s institution is not intended to contain the definitive or sole uses of albumin that might be considered for a critically ill patient. Rather, the table is intended to serve as an example of how a protocol for albumin use might be configured.

**DOSING OF FLUID ADMINISTRATION**

Since the 1940s and until the 1990s, the traditional dosing of intravenous fluids in a patient with shock was administration of a bolus of isotonic crystalloid solution of around 1500–3000 mL (or an equivalent amount of colloid). A paradigm shift occurred, at least with respect to the resuscitation of trauma patients, with the publication of a landmark study in 1994 that showed increased mortality in patients receiving aggressive preoperative fluids.\textsuperscript{75} Delayed resuscitation of fluids until the operating room was associated with increased survival (p=0.04) in patients with gunshot or stab wound injuries to the torso who had systolic blood pressure recordings less than 90 mm Hg. It was postulated that the aggressive fluid administration led to increased
bleeding by dilution of clotting factors and by clot destabilization. This led to the concept of permissive hypotension for patients with traumatic hemorrhage in which mini-boluses of fluid (250–500 mL) are given to achieve a palpable pulse or central arterial pressure recordings, just sufficient to maintain vital organ perfusion. In patients without obvious exsanguination, a fluid bolus may help differentiate simple extracellular depletion (i.e., an appropriate and relatively sustained response) from ongoing blood loss (relatively rapid recurrence of hypotension). The most appropriate dose of fluids for patients with blunt trauma may be a function of the presence or absence of hypotension before resuscitation, according to the analysis of a subset of data obtained from a multicenter prospective study of prehospital fluid administration. When more severely injured (defined as an ISS [injury severity score] greater than 15) patients with blunt trauma were divided into low-volume (less than 500 mL) or high-volume (greater than 500 mL) crystalloid administration, patients with hypotension (systolic blood pressure of at least 90 mm Hg on presentation to the emergency department) had increased mortality (HR 2.5; 95% CI, 1.3–4.9) when given high-volume crystalloids. In the patients with blunt trauma having hypotension, each 1-mm Hg increase in systolic blood pressure was associated with a 2% increase in survival (OR 1.02; 95% CI, 1.01–1.03).

The concept of permissive hypotension in fluid resuscitation traditionally has not been applied to the resuscitation of patients with nonhemorrhagic forms of shock when aggravation of blood loss was not a factor. For example, in the Surviving Sepsis Campaign guidelines published in 2013, crystalloid boluses up to 20 mL/kg (or an equivalent amount of albumin) given over 5–10 minutes were recommended for the initial resuscitation of shock; further, the authors stated that larger fluid deficits might necessitate fluid doses up to 60 mL/kg. Vasopressors were recommended in the guidelines when response to this initial fluid resuscitation was insufficient. Until recently, the use of an initial bolus dose of fluids during resuscitation was relatively unquestioned. In a study investigating African children with infection and impaired perfusion (known as the FEAST study), increased 48-hour
mortality was found with bolus administration (20–40 mL/kg over 1 hour) compared with no-bolus fluid administration, regardless of whether the fluid bolus was 5% albumin or normal saline (10.6% and 10.5%, respectively, vs. 7.3% with no bolus, p=0.003). Because the main cause of death was cardiovascular collapse, there is a suggestion that somehow fluid boluses alter normal homeostatic mechanisms in a negative way. This study was remarkable, not only for its findings but also for the methodologic problems that had to be overcome to conduct a randomized trial outside the confines of sophisticated critical care facilities. Whether the findings should change the initial fluid management of nonhemorrhagic shock in adult patients in more industrialized countries with well-equipped health care facilities is open to debate, but at a minimum, it has raised an important question that needs to be answered in future investigations.

\(^a\)Definitions:
- Clinically important edema (e.g., massive ascites and pulmonary edema)
- Large amounts of crystalloid (0.9 NaCl, lactated Ringer’s injection, etc.): > 4 L for adults or > 40 mL/kg in children
- Maximzed diuretic therapy or diuretic resistance or development of adverse drug events: furosemide equivalent 200 mg intravenously as a single bolus, 20 mg/hr as an intravenous infusion, or 500 mg/day intravenously as a total
- Hypoalbuminemia: < 1.5 g/dL in neonates < 2 wk of age OR < 2.5 g/dL for children ≥ 2
The amount of fluid compartment expansion for many crystalloids and colloids as determined in clinical investigations is often far different from the expansion predicted for these fluids using traditional factors such as hydrostatic and colloid osmotic pressure with membrane permeability coefficients (Table 2.3). Estimates of fluid distribution that do not consider leakage of colloid over time suggest that 3 or 4 times as much as normal saline are required to give the equivalent plasma expansion of albumin (4% or 5%) or 6% hydroxyethyl starch. But plasma expansion is time sensitive, with a peak usually occurring within 2 hours of fluid administration, followed by a decline phase associated with albumin (or starch) and accompanying fluid leakage to the interstitial compartment. For example, in normal volunteers administered 4 mL/kg (average 260 mL) of 7.5% sodium chloride solution over 30 minutes, plasma volume as measured by the dilution of iodine-125 (125I)-labeled albumin increased 442 ± 167 mL during the infusion to 465 ± 83 mL at the end of the monitoring period, 90 minutes from baseline. In a study of patients undergoing elective surgery, plasma expansion with 50 g of albumin given over 90 minutes as solutions of 5% (145 mmol/L sodium), 20% (100 mmol/L), or 25% albumin (100 mmol/L sodium) was compared using 131I-labeled albumin. The plasma volume increased by an estimated 500 mL in all groups, suggesting that albumin dose, not concentration, was the determining factor for intravascular expansion. This translated to about an 11-mL increase in plasma volume for each 1 g of infused albumin. Albumin has also been studied in patients with sepsis. In one study using 125I-labeled albumin, transcapillary escape of albumin was measured after the infusion of 200 mL of 20% albumin. Despite a near-doubling of serum albumin concentrations, transcapillary fluid escape was unchanged (p=0.55), suggesting no effect of albumin on vessel permeability. Furthermore, colloid osmotic pressure, which had increased quickly after albumin infusion, decreased to 50% of peak concentrations by 240 minutes. In another study, 200 mL of 20%
albumin was given by rapid infusion to patients with septic shock or controls. Albumin concentrations increased by almost 100% in the patients with sepsis receiving this dose. The estimated plasma expansion, as noted by changes in hematocrit corrected for dilution by the infused volume, was maximal at 30 minutes, which was 430 mL and 500 mL (not significantly different) in patients with sepsis and controls, respectively. However, by 15 minutes, more albumin was being lost from the intravascular compartment in patients with sepsis, and by 4 hours, 32% of the increased albumin in the patients with sepsis and 21% of the albumin in the controls (p<0.001) had shifted to the interstitial compartment, consistent with increased capillary permeability in patients with sepsis. These studies should be interpreted in light of animal studies that suggest that plasma expansion by colloids (but not normal saline) is affected by infusion rate, with greater expansion when colloids are given at a slower rate.

Table 2.3 Theoretical Fluid Distribution by Body Compartment

\[\text{Table 2.3 Theoretical Fluid Distribution by Body Compartment}\]
Based on administration of 1 L of each solution for comparative purposes only. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a short period. Numbers are approximations and likely not reflective of actual fluid distribution in critically ill patients; arrows indicate direction of fluid shift, and plus signs indicate fluid pulled from other compartments.

After distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in the interstitial compartment, and 40% is in the intravascular compartment.

These single-dose studies of plasma expansion with crystalloids and colloids suggest that the actual volume expansion associated with these fluids in critically ill patients can be substantially different from the expansion estimated by body compartment size or studies of normal healthy volunteers. This impression is further reinforced by clinical investigations that used fluid dosing regimens similar to those used in actual clinical practice. For example, in one double-blind RCT
comparing 6% hydroxyethyl starch 130/0.4 with normal saline in patients with severe sepsis (CRYSTMAS trial), the amount of normal saline required to achieve initial fluid resuscitation end points was only 24% higher than that needed for starch resuscitation. Similarly, in the landmark SAFE trial involving 6997 mixed medical-surgical ICU patients, the amount of 4% albumin required for fluid resuscitation was only 32% higher than for normal saline on study day 1, and by study day 4, there was no significant difference in study fluid needed in each group. In addition to the smaller-than-expected increases in plasma expansion with colloids in the CRYSTMAS and SAFE trials, there were no significant differences in other measures of efficacy between the crystalloid group and the colloid group.

The dosing of fluids in critically ill patients with ARDS has been evaluated in a large RCT (known as FACCT) undertaken by the National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. The study randomized 1000 patients (66% medical) with acute lung injury (now considered to have adult respiratory distress syndrome) to a conservative or liberal fluid management strategy with a primary end point of 60-day mortality. A 2 × 2 factorial design was used that allowed for a comparison of right heart catheter with central venous pressure (CVP) monitoring to guide conservative versus liberal fluid management. Other primary monitoring values were MAP (focus on fluids or vasopressors only if less than 60 mm Hg), urine output (decreased if less than 0.5 mL/kg/hour or normal if 0.5 mL/kg/hour or more), and physical examination findings (inadequate circulation if cold mottled skin with capillary refill time greater than 2 seconds) for the CVP monitoring group or cardiac index (inadequate circulation if less than 2.5 L/kg/minute) for the right heart catheter group. The study should be considered a post-resuscitation study in the sense that the mean time from ICU admission to protocol implementation averaged about 41–44 hours in both groups. The type of catheter used to guide fluid management did not influence the study findings, so all results were reported, irrespective of catheter assignment. Net fluid balance was negative in the conservative group and positive in the liberal group.
(p<0.001), which was associated with more ventilator-free days and non–ICU-stay days in the conservative group (p<0.001 for both). Although minor adverse effects (e.g., metabolic alkalosis and electrolyte abnormalities) were more common with the conservative fluid strategy, the percentage of patients requiring renal replacement therapy was actually lower (p=0.06) with the conservative approach. The study findings would appear to be relatively robust for general medical-surgical ICU patients who develop adult respiratory distress syndrome within the first 2 days of ICU admission, regardless of the fluids administered during the initial resuscitation for shock. The findings strongly suggest that lung function can be improved without sacrificing renal function using a conservative fluid administration approach. One concern with applying the results of the FACCT investigation to the clinical setting is the complicated protocol that was used for monitoring and interventions. Fortunately, a follow-up study known as FACTT Lite has suggested that a less complicated protocol based on CVP and urine output recordings yields similar beneficial results.86

MONITORING OF RESUSCITATION

Many patients with shock are first seen in the emergency department, and the appropriate monitoring parameters depend on factors such as type and severity of shock. For a patient with traumatic hemorrhage, the monitoring may be limited to an assessment of heart rate and mental status as indicators of more severe blood loss necessitating immediate transfer to the operating room for definitive control of bleeding. For a patient with possible septic shock, the monitoring should include blood collections for lactate concentration and cultures in addition to vital signs, oxygen saturation, and urine output (by urine catheter) determinations. The challenge is early identification of hypovolemia and fluid responsiveness after compensatory changes have begun to fail, as indicated by parameters such as hypotension and decreased urine output. For patients in the ICU setting with impending or overt shock, there is general consensus on the need for an appropriate physical examination in conjunction with assessments of
mental status, temperature, blood pressure, heart rate, respiratory rate, fluid balance, urine output, weight, and basic laboratory monitoring that includes electrolytes, complete blood cell count, glucose, lactate, serum BUN, and creatinine. No single parameter in isolation is sufficient, some parameters are not immediately available (e.g., laboratory values), and consensus begins to fade as the type of monitoring technique becomes more invasive and more expensive (Table 2.4 and Table 2.5). Some of the skepticism associated with more invasive monitoring tools originates in previous widespread use of the right heart catheter in many ICU settings, given the perceived advantages of titrating fluids and cardiovascular medications to hemodynamic indices (e.g., cardiac index) using this technique. Subsequently, large-scale studies were unable to find a clinically important outcome benefit with using right heart catheters. Nevertheless, some still argue that the lack of outcome improvement in some of these studies occurred because of a lack of appropriate patient selection and a lack of training and expertise by many of the physicians using the catheters. In addition, it can be argued that the use of right heart catheters is appropriate in selected critically ill populations (e.g., cardiac surgery patients), which were not the focus of the large randomized studies.

**More Sophisticated and/or Invasive Monitoring Techniques**

During episodes of hypovolemic shock, a decreasing output with increased systemic vascular resistance is noted by a reduced pulse pressure (systolic minus diastolic pressure is less than 25% of systolic) that should correct with appropriate resuscitation. In hypovolemic patients receiving conventional mechanical ventilation with tidal volumes of at least 8 mL/kg, it is possible to monitor the rise and fall in arterial pressure associated with the rise and fall in intrathoracic pressure, a
condition known as reverse pulsus paradoxus (to contrast it with the pulsus paradoxus that occurs in a spontaneously breathing patient). Maximum minus minimum systolic pressure variations or pulse pressure variations greater than 10% are considered dynamic indicators of fluid responsiveness. More sophisticated technologies have used stroke volume variation (also known as pulse contour or waveform analysis) for cardiac output determinations.

Central venous pressure is often recommended as one of the more important parameters used to assess intravascular volume status during fluid challenges, but it has important limitations as an indicator of fluid responsiveness because it is influenced by abdominal pressure, pleural pressure, and different forms of mechanical ventilation. Vincent and Weil have reviewed issues related to fluid challenges in critically ill patients with hypovolemia and stated what they considered misconceptions regarding monitoring parameters such as CVP:90

- “Fluid administration should be withheld because the central venous pressure is high.”
- “Fluid administration should be withheld because there is evidence of lung edema on the chest roentgenogram.”
- “Fluid administration should be withheld because the patient has already received a large volume in a short time interval.”
- “Tachycardia is due to fluid deficit and should prompt increases in fluid administration.”
- “I gave fluids to increase the central venous pressure to 12 mm Hg to exclude an underlying hypovolemia.”

Vincent and Weil expressed concern with using filling pressures as indices of effective resuscitation but stated that monitoring of CVP is “acceptable” as a safety limit for fluid challenge, assuming no preexisting heart or lung disease. They proposed a modified “2–5 rule” (modified from previous technique) in which a fluid challenge (e.g., 500 mL of isotonic crystalloid over 30 minutes) is administered in conjunction with an ongoing monitoring of efficacy and safety end points, including CVP. If the efficacy end points are reached, or if CVP
at any point increases to greater than 5 mm Hg above baseline or reaches a predefined safety limit such as 15 mm Hg, fluid administration should be discontinued.

In addition to a catheter to monitor CVP, various types of peripheral venous, central venous, and arterial catheters have been placed to assess components of oxygen delivery and oxygen consumption in conjunction with fluid and drug administration in critically ill patients. The prototype central catheter was the right heart catheter (a.k.a. pulmonary artery or Swan-Ganz catheter) that used indicator dilution to assess several cardiorespiratory variables, including cardiac output. An indicator is injected and monitored for dilution (y-axis) by time (x-axis) that allows the calculation of area under the curve (AUC). The usual indicator is fluid temperature, so the technique is known as thermodilution, but other dyes or markers have been used for the same purpose. The cardiac output is subsequently calculated by the dose of indicator administered (times a constant) divided by the AUC. Modern catheters can provide continuous monitoring (Box 2.4). In addition, less invasive peripheral artery catheters have been used to estimate stroke volume or cardiac output through a technique called waveform analysis, in which algorithms are used to relate peripheral to central pressures.

Apart from a general consensus (albeit without much evidence) that allows for catheter placement to monitor blood pressure and possibly CVP in patients with shock, there is little evidence from a cost-effective standpoint to justify the routine use of other catheters for the hemodynamic monitoring of critically ill patients undergoing resuscitation. The risks associated with monitoring catheters varies by degree of invasiveness, but neither the older, more invasive central catheters (e.g., right heart catheter) nor the newer, less invasive central (e.g., internal jugular or femoral vein) or peripheral catheters have been shown to improve clinically important end points in a general critical care population in adequately powered randomized studies. Some would argue that the catheter used in the trial by Rivers et al. and the Early Goal-Directed Therapy (EGDT) Collaborative Group is an exception to the latter statement, because there was a statistically significant reduction in mortality in the EGDT group with the use of a special catheter capable of continuous central venous oxygen
saturation monitoring (Scvo₂). In contrast to Svo₂, which requires placement of a right heart catheter, Scvo₂ measurements can be obtained through a special catheter inserted as a probe through a lumen of a traditional central venous catheter or as an integrated system placed at the same site as a traditional central venous line (i.e., internal jugular, femoral, or subclavian vein). However, the applicability of this study to the ICU setting is unclear because of the following: the study was limited to patients with severe sepsis or septic shock who were treated in an emergency department, patients received several other interventions by protocol in the EGDT group (so was it the protocol, not the catheter per se?), and monitoring with the catheter was discontinued before ICU admission. Furthermore, the mortality rate in the control group was unexpectedly high compared with the EGDT group (46.5% vs. 30.5%, respectively, p=0.009), which raised questions about the single study site and/or randomization process. However, the strongest argument against any unique benefit associated with Scvo₂ monitoring is based on more recent randomized multicenter trials of EGDT monitoring by the ProCESS investigators from the United States, the ARISE investigators from the Australian and New Zealand Intensive Care Society (ANZICS) Clinical Trials Group, and the ProMISe investigators from the United Kingdom. In the ProCESS (n=1341), ARISE (n=1600), and ProMISe (n=1260) studies, the investigators tried to follow the EGDT protocol from the original study by Rivers et al. with continuous Scvo₂ monitoring during the first 6 hours after patient presentation to the emergency department. In ProCESS and ProMISe, Scvo₂ and CVP monitoring were required in the EGDT group, and continuous arterial pressure monitoring was recommended but not required. The usual care groups in ProCESS, but not ProMISe, received protocol-based care. In ARISE, Scvo₂, CVP, and continuous arterial pressure monitoring were required in the EGDT group, but the usual care group did not receive protocol-based care; thus, CVP and arterial pressure monitoring were allowed if deemed appropriate by the treating clinicians. Otherwise, the EGDT protocols were similar, as were the study results. There was no significant difference between the EGDT and the usual therapy groups.
for the primary end points of 60-day mortality in ProCESS (p=0.83) and 90-day mortality in ARISE and ProMISe (p=0.90 for both studies). Similarly, there were no significant differences in any of the major secondary end points, including length of stay. As with the right heart catheter, central venous catheters placed for continuous monitoring have yet to show an evidence-based indication.

**Box 2.4. Catheters Based on Indicator Dilution**

**Right heart catheter with thermistor for intermittent thermodilution**

Cold fluid injected near right atrium with detection in pulmonary artery

**Right heart catheter with thermistor for continuous (actually averaged values) thermodilution: Vigilance®**

Heat energy by random off/on pattern with detection in pulmonary artery

**Transpulmonary intermittent thermodilution: PiCCO®**

Cold fluid injected near right atrium (internal jugular or right subclavian) with detection by thermistor tip in femoral/axillary artery

**Transpulmonary lithium dilution: LiDCO®**

Same principle as PiCCO® but uses lithium solution, not cold fluid

An alternative to both CVP and other forms of invasive hemodynamic monitoring used to assess fluid responsiveness is ultrasonography or echocardiography, usually transthoracic echocardiography (TTE). Not only is TTE monitoring noninvasive and performable by non-cardiologists, but it can also be considered a
dynamic (albeit not continuous) rather than static form of monitoring that estimates fluid responsiveness by evaluating the collapsibility of the inferior vena cava. The most clear-cut indicator of fluid responsiveness is complete vessel collapse, although less obvious collapse may be detected by having the patient sniff (rapidly and audibly drawing in air through the nose) and assessing the percent collapse because this maneuver causes a negative inspiratory pressure. In addition to providing an assessment of volume status, TTE can be used by critical care practitioners to assess cardiac function and determine whether a patient with shock has a component of left ventricular dysfunction that might be amenable to a form of therapy other than fluids (e.g., inotropes), or determine whether a patient has pericardial effusion or tamponade. Other forms of TTE evaluation include transaortic stroke volume variation with passive leg raising or with respiration. One systematic review found that all three of these forms of TTE (i.e., inferior vena cava diameter and transaortic stroke volume variation with passive leg raising or with respiration) had very good predictive ability (receiver operating curve greater than 0.9) and could be used in patients with spontaneous breathing efforts and arrhythmias. Transesophageal echocardiography has potential advantages with respect to image quality but requires more specialized training for appropriate use, and patients must be sedated. As with invasive forms of hemodynamic monitoring for shock or impending shock, there is little evidence and few data on cost-effectiveness to support the routine use of more specialized monitoring techniques like TTE.

**General Recommendations for Monitoring**

A task force of the European Society of Intensive Care Medicine has produced a series of statements relevant to the monitoring of all forms of circulatory shock. Most recommendations are based on either ungraded or the lowest level of evidence; nevertheless, they provide a useful consensus guidance to the clinician. Some of the more salient points include:
- Individualizing target blood pressure (initial target MAP of 65 mm Hg or more) on the basis of factors such as uncontrolled bleeding in the absence of brain injury (lower MAP target) or in patients with sepsis with a history of hypertension (higher MAP target if evidence of clinical improvement)

- Use of several variables (monitoring of heart rate, blood pressure, temperature, physical examination, urine output, and mental status considered best practice; lactate in all cases of suspected shock) for assessment, with dynamic preferred to static measurements

- Use of arterial and central venous catheter monitoring when shock is not responsive to initial therapies or when vasopressors are required

- Use of echocardiography preferred when more advanced monitoring is needed; reserving more invasive forms of monitoring, such as right heart catheterization, to complex patients with severe or refractory shock

**MAINTENANCE FLUID ADMINISTRATION**

The National Institute for Health and Care Excellence of the United Kingdom has published guidelines for intravenous fluid administration in hospitalized adults. Although the guidelines were not specific to critically ill patients, they contain a useful algorithm of factors to consider during maintenance fluid administration (Figure 2.1) and a useful figure for estimating electrolyte losses from the body (Figure 2.2). Assuming relatively normal electrolyte and glucose panels without organ dysfunction (e.g., renal failure) that might dramatically alter maintenance requirements, an example of a typical initial intravenous maintenance fluid would be 5% dextrose in 0.22% sodium chloride with 30 mEq/L of potassium chloride at a rate usually not exceeding 25–30 mL/kg/day (using an ideal or lean body weight for dosing patients with obesity because plasma volume does not increase proportionally with excess weight gain), with lower rates for patients with, or predisposed
to, fluid-related complications such as ARDS. In patients with complications such as ARDS, a simplified version (based on MAP, CVP, and need for vasopressors) of the monitoring protocol used for conservative fluid administration in the FACTT trial resulted in more fluid accumulation but similar clinical outcomes (FACTT Lite trial).  

**APPROPRIATE USE OF CRYSTALLOIDS AND COLLOIDS IN CRITICALLY ILL PATIENTS**

Of the various crystalloids and colloids that have been studied in critically ill patients, the hydroxyethyl starch products have no substantial evidence of superior efficacy compared with other commonly used intravenous fluids. Furthermore, safety concerns have been raised in every large randomized study with single fluid-to-fluid comparisons. Therefore, as with gelatin and dextran products, the routine use of hydroxyethyl starch products as a resuscitation fluid for critically ill patients cannot be justified. Indeed, leading researchers in the field have even raised ethical issues about informed consent when hydroxyethyl starch solutions are used in ongoing and future research investigations, and they have recommended that the products be withdrawn from the market.

The proper role of albumin in critically ill patients is becoming better defined, given studies of the properties of exogenous albumin and the efficacy and safety findings in large randomized investigations. With respect to fluid resuscitation in general mixed medical-surgical ICU populations, albumin has no convincing evidence of superiority over less expensive isotonic crystalloid solutions, so it should be considered a second-line agent, if used at all. Similarly, there is little justification for albumin use in trauma patients, and it should be avoided in patients with traumatic brain injury. Isotonic crystalloid solutions remain the resuscitation fluid of choice in patients with traumatic brain injury. In patients with severe sepsis and septic shock, albumin or isotonic crystalloids are options for resuscitation according to current practice guidelines, but evidence of albumin superiority over crystalloids is weak at best, so clinicians should feel no compulsion to consider albumin a
first-line option, given its higher cost. Albumin use is recommended in consensus-based guidelines for other subsets of ICU populations; however, with the notable exception of spontaneous bacterial peritonitis, these uses are based on low-level evidence and should be considered on a patient-specific basis.

In the not-too-distant past, the choice of fluid in the ICU setting was largely framed in terms of isotonic crystalloid versus colloid solutions. More recently, the specific composition of electrolytes in crystalloid and colloid solutions has received attention by the medical community. There is increasing concern about excessive administration of certain electrolytes, most notably chloride. This concern is reflected in changes in some resuscitation guidelines that now recommend more balanced isotonic crystalloid solutions over normal saline. Table 2.6 lists some of the more applicable systematic reviews and guidelines that pertain to resuscitation and that are likely to undergo periodic updating as new evidence arises. Finally, Box 2.5 provides some overarching considerations concerning fluid administration in critically ill patients.

The focus of this chapter has been on fluid resuscitation, but vasoactive medications are also used in the hypotensive patient. The appropriate use of vasoactive agents will be discussed in other chapters, but in all forms of shock, proper attention must be paid to maintaining intravascular volume by fluid administration, particularly during the early stages of resuscitation. This is true even for septic shock that is defined as persistent hypotension after adequate fluid resuscitation. In a recent retrospective evaluation of a large observational database, there was a significant ($p<0.0001$) interaction between fluids and use of vasoactive agents. Mortality rates were lowest in patients who received delayed use (1–6 hours after shock onset) of vasoactive agents.

**FUTURE DIRECTIONS**

Ideally, future large RCTs will be conducted that provide evidence for or against the use of specific fluids and monitoring tools in critically ill patients. Unfortunately, the design of these trials is fraught with
challenges beyond usual issues, such as sample size and blinding. As discussed earlier, both colloid fluids and crystalloid fluids vary in electrolyte composition, and it has been established that some commercially available exogenous albumin preparations do not have the same physicochemical characteristics as endogenous albumin. Table 2.7 shows some of these challenges using landmark studies involving albumin as an example, but the comments are applicable to studies using other fluids such as high-chloride-containing crystalloid solutions.\textsuperscript{107,108} One challenge is deciding which patients to study and with which study design. The three large, pragmatic studies involving albumin enrolled patients in multidisciplinary medical and surgical ICU settings and left all decisions regarding concomitant crystalloid fluids to the clinicians caring for the patients.\textsuperscript{53,62,107} With a large sample size, the advantage to this approach is that the findings are more likely to be generalizable. A disadvantage to this approach is that a potential beneficial effect in a particular subset of patients cannot be ruled out, as exemplified by the reductions in mortality found when albumin was administered to patients with spontaneous bacterial peritonitis.\textsuperscript{66} Patient eligibility requirements and time to study entry are other factors that may complicate study conclusions. For example, arguments can be made for administering albumin earlier (e.g., early stage of shock before multiple organ dysfunction) or later (e.g., ARDS or burn injury after capillary permeability is restored) during ICU stay. If administered later during ICU stay, investigators must consider how pre-study (prehospital, emergency department, operating room, ward if transfer, and/or ICU stay before albumin administration) colloid or crystalloid administration might influence study end points. The appropriate dose, duration, and end points of albumin administration are other questions open to debate, particularly if the presumed beneficial mechanism of action of albumin being tested is something other than its oncotic and plasma expansion properties. There is no single right or wrong approach to any of these considerations, but the important point is that they must be considered during study design and later when interpreting study results.

Box 2.5. Overarching Considerations for Fluid Administration in Critically Ill Patients

Have established policies and protocols for fluids (and medications) that should be given by central rather than peripheral intravenous lines.

For dilution of fluids such as 25% albumin, osmolarity and tonicity issues must be considered.

Appreciate that much of the terminology of fluids is not standardized (e.g., hypertonic saline is not synonymous with 3% sodium chloride solution but is any sodium chloride solution above 0.9%; a balanced electrolyte solution does not refer to a specific fluid).

Electrolyte composition differences of crystalloid and colloid solutions must be considered in clinical investigations.
Clinical trials that combine disparate fluids into one group (e.g., colloids vs. crystalloids) will have results that are difficult to interpret.

For intravenous gelatin, dextran, and starch products, the benefits do not outweigh the risks in most, if not all, critically ill patients.

Spontaneous bacterial peritonitis is the only disease state in which albumin has been shown to reduce unadjusted mortality (evidence from only one randomized controlled trial).

Albumin is more likely to cause harm than benefit in the resuscitation of patients with traumatic brain injury.

Commercially available albumin does not have the same physicochemical characteristics as endogenous albumin, so mechanistic arguments for exogenous albumin administration based on endogenous albumin properties are not a substitute for randomized trials.

Hypertonic sodium chloride has no benefit over isotonic crystalloid solutions for fluid resuscitation and is a concentrated electrolyte solution with the potential for medication errors and adverse drug events.

In patients with severe traumatic hemorrhage, the definitive intervention is surgery for bleeding control, not plasma expansion.

Colloids do not provide the expected plasma expansion suggested by models of fluid distribution in body compartments.

There is increasing concern that administering large bolus doses of fluids during the initial phase of resuscitation of shock may negatively affect normal adaptive homeostatic responses.

There is increasing evidence to suggest that fluids more balanced in electrolytes, particularly chloride, are preferable for the initial resuscitation of patients with shock.
Fluid administration post-resuscitation must be individualized according to patient-specific conditions.

For most patients who develop ARDS in the post-resuscitation phase of management, fluid restriction is indicated.

No high-level evidence supports the use of more invasive, costly catheters as part of routine monitoring of shock.

No single monitoring parameter in isolation is adequate for assessing the adequacy of resuscitation.

ARDS = acute respiratory distress syndrome.

Appendix 2.1. Examples of Osmolarity Calculations

Here is an example that shows the concept of osmolarity using an albumin solution that is presumed to be formulated in a normal saline solution. Assume we have 50 mL of a 25% (i.e., 12.5 g per 50 mL or 25 g per 100 mL) albumin solution in 0.9% sodium chloride; the osmolarity using albumin is calculated as follows:

1 mole of albumin = 1 eq wt of albumin = 70,000 g
1 mmol of albumin = 1 mEq wt of albumin = 70 g

So,

\[
\frac{1 \text{ mEq wt}}{70 \text{ g}} = \frac{X}{12.5 \text{ g}}
\]

\[
X = 0.17857 \text{ mEq of albumin in 50 mL of 25%}
\]

\[
\frac{0.17857 \text{ mEq}}{50 \text{ mL}} = \frac{X}{1000 \text{ mL}}
\]

\[
X = 3.57 \text{ mEq or mOsm of albumin in 1000 mL}
\]

Or an easier way,

There is 250 g/L of albumin in this solution, so:

\[
\frac{1 \text{ mEq}}{70 \text{ g}} = \frac{X}{250 \text{ g}}
\]

\[
X = 3.57 \text{ mEq or mOsm of albumin in 1000 mL}
\]

For the sodium chloride component, there is 0.45 g in the 50-mL (or 0.9 g per 100 mL) solution:

1 mole of sodium chloride = 1 eq wt of sodium (23 g) + 1 eq wt of chloride (35.5 g) = 58.5 g
1 mmol of sodium chloride = 1 mEq wt of sodium + 1 mEq wt of chloride = 0.0585 g

So,
Or an easier way,

There is 9 g/L of sodium chloride in this solution, so:

\[
\frac{2 \text{ mEq wt}}{0.0585 \text{ g}} = \frac{X}{0.45 \text{ g}} \quad X = 15.4 \text{ mEq of sodium and chloride in 50 mL}
\]

\[
\frac{15.4 \text{ mEq}}{50 \text{ mL}} = \frac{X}{1000 \text{ mL}} \quad X = 308 \text{ mEq or mOsm of sodium and chloride in 1000 mL}
\]

Because 1 mEq = 1 mOsm for albumin (not ionized), albumin contributes 3.57 mOsm/L to the total osmolarity of the commercially available 25% solution. Assuming complete ionization, the 154 mEq/L of sodium chloride in this same solution contributes 308 mOsm/L for a total osmolarity of 311.57 mOsm/L.

A variety of online calculators are available on the Internet for determining the osmolarity of various electrolytes, and some calculators are available that determine the osmole content of complex admixtures (e.g., www.globalrph.com), but any calculation should be verified by at least one other method.
Chapter 3

Electrolyte Disorders in the Critically Ill Population

Jeffrey J. Bruno, Pharm.D., BCPS, BCNSP; and Todd W. Canada, Pharm.D., FASHP, FTSHP, BCNSP

LEARNING OBJECTIVES

1. Distinguish the homeostatic mechanisms responsible for normal sodium, potassium, magnesium, phosphorus, and calcium balance in critically ill patients.

2. Provide the most common etiologies of hypo- and hypernatremia, hypo- and hyperkalemia, hypo- and hypermagnesemia, hypo- and hyperphosphatemia, and hypo- and hypercalcemia in critically ill patients.

3. Determine clinical estimates of replacement therapy involving sodium, potassium, magnesium, phosphate, and calcium in the critically ill population.

ABBREVIATIONS IN THIS CHAPTER

ADH  Antidiuretic hormone
AMI  Acute myocardial infarction
ATP  Adenosine triphosphate
INTRODUCTION

This chapter provides a concise and clinically oriented overview of sodium, potassium, magnesium, phosphorus, and calcium derangements. Emphasis is placed on the clinical management of such disorders at the bedside, and when available, pertinent primary literature is discussed. Areas for which primary literature does not exist are clearly delineated, with guidance provided by published expert opinion and sound clinical judgment.

SODIUM AND WATER HOMEOSTASIS

Before discussing sodium disorders, it is important to have a firm understanding of total body water (TBW) and serum osmolality, given the relationship among these three entities. Overall, about 50% of body weight in females and elderly males and 60% in non-elderly males consists of water. Most TBW is located in the intracellular space (60%). The remaining 40% of TBW is found in the extracellular space, with 25% intravascular and 75% interstitial.
Under normal physiologic conditions, water moves between the extracellular fluid (ECF) and the intracellular fluid (ICF) in response to osmotic gradients. Osmotic gradients are generated by differences in the concentration of effective osmoles (i.e., solutes than cannot freely cross cell membranes) between the ECF and the ICF. Sodium and chloride are the primary effective osmoles responsible for ECF osmolality, whereas potassium and phosphate primarily drive ICF osmolality. Water can freely or passively move across cell membranes and will move from areas of low to high osmolality in an attempt to maintain a normal serum osmolality (i.e., 275–290 mOsm/kg). Serum osmolality can either be directly measured by laboratory analysis or estimated using equation 3.1. Discrepancies can arise between the measured and the calculated serum osmolality when effective osmoles not accounted for in the equation are administered exogenously and accumulate (e.g., propylene glycol from lorazepam or ethylene glycol toxicity), resulting in the development of an osmolar gap.

\[
\text{serum osmolality (mOsm/kg) = } 2 \times \text{serum sodium (mEq/L)} + \text{serum glucose (mg/dL)/18 + blood urea nitrogen (mg/dL)/2.8 (equation 3.1)}
\]

Mechanisms exist to facilitate sodium and water homeostasis, thereby maintaining a normal serum osmolality. The hypothalamus plays an integral role, with as little as a 1% change in serum osmolality triggering homeostatic mechanisms. In the setting of increased serum osmolality, the hypothalamus stimulates the thirst mechanism as well as the release of arginine vasopressin (AVP), or antidiuretic hormone (ADH), from the posterior pituitary gland. Unfortunately, in many critically ill patients, the thirst mechanism may be of little utility given the limitations imposed by acute illness on the self-administration of fluids, leaving both fluid administration and fluid composition at the discretion of the clinician(s). Antidiuretic hormone works by binding to vasopressin 2 (V₂) receptors on renal tubular epithelial cells. This results in the insertion and opening of aquaporin 2 channels, facilitating reabsorption of water back into the systemic circulation and thereby decreasing serum osmolality. However, a change in serum osmolality is not the
only trigger for mediators of sodium and water homeostasis. For example, hypotension triggers arterial baroreceptors in the carotid sinus and glomerular afferent arterioles, subsequently activating the renin-angiotensinaldosterone system. Activation of the renin-angiotensin-aldosterone system will induce sodium and water retention as well as ADH release, irrespective of serum osmolality. In addition, ADH release can be triggered by pain and stress, such as during the immediate postoperative period.

**HYPONATREMIA**

Hyponatremia is defined as a serum sodium concentration less than 135 mEq/L. Retrospective studies indicate that hyponatremia affects 20%–38% of hospitalized patients and 11%–38% of critically ill patients. Prevalence variations are likely associated with differences in diagnostic threshold, patient populations, and reporting of intensive care unit (ICU)-admission, ICU-acquired, or spot check hyponatremia.

**Pathophysiology and Classification of Hyponatremia: Isotonic, Hypertonic, and Hypotonic**

Hyponatremia is usually associated with a hypotonic state and is much less commonly observed in a hypertonic or isotonic setting. In the past, serum sodium concentrations were determined using flame photometry. With such practice, elevated concentrations of lipids (e.g., hypertriglyceridemia) and proteins (e.g., hyperproteinemia in multiple myeloma) led to falsely low serum sodium concentrations or pseudohyponatremia. Measurement of serum sodium by ion-specific electrodes has made pseudohyponatremia nonexistent. Isotonic hyponatremia is characterized by a serum osmolality of 275–290 mOsm/kg and a serum sodium less than 135 mEq/L. Systemic absorption of irrigation solutions, such as dextrose or 1.5% glycine, can result in isotonic hyponatremia, as seen after transurethral resection of the prostate.
Hypertonic hyponatremia is characterized by a serum osmolality greater than 305 mOsm/kg and a serum sodium less than 135 mEq/L. Common causes of hypertonic hyponatremia include hyperglycemia and infusion of glycerin- or mannitol-containing solutions.\textsuperscript{1,2} Essentially, the increase in or introduction of effective osmoles other than sodium to the ECF leads to a rise in serum osmolality, movement of free water from the ICF to the ECF, and subsequent hyponatremia. Management of hypertonic hyponatremia involves correcting the underlying cause (i.e., minimizing or removing the non-sodium effective osmole). Traditionally, for each 100 mg/dL increase in serum glucose above 100 mg/dL, serum sodium was expected to fall by 1.6 mEq/L\textsuperscript{13}; however, others have shown a correction factor of 2.4 mEq/L to be more appropriate.\textsuperscript{14} Equation 3.2 can be used to determine a corrected serum sodium in the presence of hyperglycemia. Clinicians should be cognizant that the fall in serum sodium with hyperglycemia is nonlinear and can be as high as 4 mEq/L when the blood glucose is greater than 400 mg/dL.\textsuperscript{14}

\[
\text{corrected serum sodium (mEq/L) = serum sodium (mEq/L) + 0.024 [serum glucose (mg/dL) - 100]} \\
\text{(equation 3.2)}\textsuperscript{14}
\]

Hypotonic hyponatremia, characterized by a serum osmolality less than 275 mOsm/kg and a serum sodium less than 135 mEq/L, is the most common type of hyponatremia and therefore the most clinically relevant. Hypotonic hyponatremia is further classified into hypovolemic, euvolemic, or hypervolemic depending on the patient’s fluid status.\textsuperscript{1,4} The differential diagnosis for hypotonic hyponatremia is discussed later in this chapter.

**Clinical Manifestations**

Clinical manifestations of hyponatremia predominantly include disorders of the central nervous system (CNS) and vary widely among patients depending on the degree of hyponatremia and duration of development. Overall, it is safe to assume that the greater the
decrease in serum sodium from baseline and the more rapid the decline, the greater the shift of water from the ECF to the ICF, the greater the degree of cerebral edema, and the greater the probability for symptom development. Within minutes of hyponatremia development, brain cells try to accommodate by the efflux of sodium and potassium ions to the extracellular space (rapid adaptation); however, movement of organic osmolytes to the extracellular space (slow adaptation) does not occur until 48 hours or more. Thus, patients with acute hyponatremia (onset less than 48 hours) are at the highest risk of severe neurological sequelae associated with cerebral edema, including vomiting, somnolence, neurogenic pulmonary edema, seizures, coma, and potential fatal brain herniation. The risk of herniation is greatest when acute hyponatremia develops over several hours. Other potential neurological symptoms include nausea without vomiting, confusion, and headache. In contrast, patients in whom hyponatremia is chronic (i.e., develops over 48 hours or more) are less prone to cerebral edema and herniation. These patients typically have minimal brain swelling and present with malaise, fatigue, cramps, confusion, and/or falls. A 10% incidence of seizures has been reported when the serum sodium concentration falls below 110 mEq/L in this population. Osteoporosis and fractures can also be seen with chronic hyponatremia.

**Morbidity and Mortality**

Hyponatremia has been associated with an increased risk of hospital mortality in several retrospective evaluations and in a meta-analysis. Of interest, some reports show a significantly increased risk of death among patients with mild or moderate, but not severe, hyponatremia compared with patients who are normonatremic. In a single-center retrospective review of almost 46,000 episodes of hyponatremia (less than 135 mEq/L), Chawla and colleagues showed a bell-shaped curve between the severity of hyponatremia and mortality, with the following specific rates: 4% (less than 110 mEq/L), 8% (110–114 mEq/L), 11% (115–119 mEq/L), 11% (120–124 mEq/L), 10%,
Furthermore, in an evaluation of patients who died with a serum sodium less than 120 mEq/L (n=53), the average Charlson comorbidity index was 5.5 (i.e., high severity of illness); 66% of patients had correction in serum sodium to 128 mEq/L or more, and only 4% presented with hyponatremia-related seizures with one case of brain herniation. In contrast, the authors’ review of 32 survivors with a serum sodium concentration less than 110 mEq/L showed a low severity of illness (Charlson comorbidity index of 1.8), serum sodium less than 120 mEq/L 24 hours after the lowest serum sodium in 75%, a 9% incidence of hyponatremia-related seizures, and medications (e.g., thiazide diuretics, selective serotonin reuptake inhibitors) as the predominant etiology. Although limited information was provided regarding the actual rate of sodium correction from hyponatremia, it may be speculated that patients die with (i.e., as a concomitant factor of their underlying illness), in contrast to die from hyponatremia. In a retrospective review of more than 13,000 serum sodium measurements from critically ill patients included in the Extended Prevalence of Infection in Intensive Care (EPIC II) study, logistic regression revealed an overall increased risk of death among patients with mild (130–134 mEq/L), moderate (125–129 mEq/L), and severe hyponatremia (less than 125 mEq/L). However, among patients with severe hyponatremia, a significantly increased risk of death was only observed among the subset of patients admitted with this disorder (odds ratio [OR] 3.79; 95% confidence interval [CI], 1.66–8.61) in contrast to those who were in the ICU at the time of evaluation (OR 1.62; 95% CI, 0.86–3.05). Of note, resolution of hyponatremia during hospitalization may help mitigate the increased mortality risk.

Assessment

Once hyponatremia is identified, the first step in assessment is to determine whether the patient is symptomatic or asymptomatic. Patients with severe neurological sequelae (e.g., vomiting, seizures, coma) should promptly receive treatment without delaying for further
assessments (see Severely Symptomatic Hyponatremia section). Next, it should be determined whether the hyponatremia is acute or chronic. This can be done by a simple trending of the patient’s serum sodium concentration for a given period (e.g., 2–14 days), if available. If the duration is unclear (i.e., no prior laboratory results and no signs of an acute etiology), hyponatremia should be presumed as chronic to avoid the adverse consequences associated with too rapid of a correction, most notably osmotic demyelination syndrome (ODS). Chronic hyponatremia should trigger consideration of etiologies that are persistent versus episodic in nature, such as syndrome of inappropriate antidiuretic hormone (SIADH) from malignancy or long-term thiazide therapy in contrast to acute vomiting. A thorough physical examination should be performed together with a review of the patient’s history and fluid balance (if available, a minimum of 2 days) before hyponatremia development. These steps may be sufficient for rather obvious etiologies of hyponatremia (e.g., dry mucus membranes in the setting of increased nasogastric [NG] tube output, consistent with hypovolemic hypotonic hyponatremia), and treatment can be instituted accordingly.

If the hyponatremia classification and etiology are not apparent from the previous steps alone, serum osmolality, urine osmolality, and urine sodium concentrations should be ordered. Serum osmolality will allow the clinician to distinguish between hypertonic (greater than 290 mOsm/kg), isotonic (275–290 mOsm/kg) and hypotonic (less than 275 mOsm/kg) hyponatremia. In hypotonic hyponatremia, the urine osmolality and urine sodium results should be coupled with the physical examination findings indicative of the patient’s fluid status (i.e., hypovolemic, euvolemic, or hypervolemic) to determine the potential etiology and subsequent intervention. Of interest, although fluid status should routinely be assessed, misjudgment is common. In addition, clinicians should be cautioned regarding the interpretation of urine sodium concentrations because many medications administered in the critically ill population can influence these results, rendering them unreliable. Some of these medications include diuretics (thiazide and loop diuretics), sodium chloride tablets, mannitol, and corticosteroids. According to the results of these urine studies, other laboratory tests
(e.g., serum cortisol, thyroid stimulating hormone) may be needed to assist with the differential diagnosis. A diagnostic algorithm for hypotonic hyponatremia is provided in Figure 3.1. Clinicians should note that many hyponatremia algorithms have been published and that slight variations in the threshold values for hyponatremia, urine sodium, and/or urine osmolality exist. Of interest, use of an algorithm versus non-guided senior physician evaluation of hyponatremia resulted in an increased ability to properly diagnose and categorize hypotonic hyponatremia.

**Management**

The treatment goals for hyponatremia are to prevent or provide relief of symptoms while avoiding complications associated with overcorrecting or correcting too rapidly (i.e., ODS). Unfortunately, data are limited regarding the acute management of hyponatremia, with most studies retrospective in nature and, for the most part, of low-quality methodology. Nevertheless, clinicians must provide therapeutic interventions at the bedside to care for these patients. This section will summarize the available data for the treatment of hypotonic hyponatremia, including treatment of the severely symptomatic patient; recommended serum sodium correction rates; and a brief discussion on addressing the underlying etiology. Osmotic demyelination syndrome will be discussed first, given the concern for iatrogenic development while treating hyponatremia and avoidance of ODS when determining serum sodium correction rates.
Prevention of Osmotic Demyelination Syndrome

In 1976, Tomlinson and colleagues described the development of central pontine and extrapontine myelinolysis in two women with profound hyponatremia after treatment with 3% sodium chloride and a subsequent rise in serum sodium of 25 mEq/L and 32 mEq/L by 48 hours. This observation was later confirmed in experimental animal models of chronic hyponatremia after rapid serum sodium correction.
Overall, demyelination occurs secondary to shrinkage of brain cells. As explained earlier, the brain adapts to the presence of hyponatremia through the loss of organic osmolytes in an attempt to minimize cerebral edema. Upon rapid correction of hyponatremia, the brain is unable to reclaim the lost organic osmolytes at a rate sufficient to keep up with the rise in serum sodium; thus, water shifts from the ICF to the ECF, leading to brain cell shrinkage and ultimately demyelination. Demyelination is characterized by a biphasic illness, termed ODS, that can occur 1–7 days after serum sodium correction. Initially, patients experience recovery of symptoms associated with hyponatremia only to later have other neurological sequelae, even in the presence of normonatremia, including seizures, behavioral abnormalities, movement disorders, and/or a “locked-in” phenomenon characterized by the inability to move, speak, or swallow. Patients may recover, have permanent disability, or even die. Osmotic demyelination syndrome is predominantly a concern for patients presenting with chronic hyponatremia.

The absolute rise in serum sodium that will induce demyelination and the development of ODS is unknown, and recommended serum sodium correction thresholds are predominantly based on case reports and case series that show avoidance of ODS. In 1986, a review of 51 patients with hyponatremia revealed no cases of ODS in those with a correction of serum sodium less than 12 mEq/L/day (n=13), whereas 37% of patients (n=38) in whom sodium was corrected by greater than 12 mEq/L/day developed or were suspected to have developed ODS. Current serum sodium correction thresholds for patients with chronic hyponatremia follow these observations. Even though ODS is most likely to occur in patients with chronic hyponatremia, concern still exists, and caution must be exercised, in patients with acute hyponatremia. Finally, patients who are malnourished, have a history of alcoholism and/or liver disease, are hypokalemic, or have a serum sodium less than 105 mEq/L are considered at high risk of ODS.

**Note:**

- NaCl = sodium chloride; SIADH = syndrome of inappropriate antidiuretic hormone; $V_2$ = vasopressin type 2.
Hyponatremia associated with severe neurological symptoms (e.g., vomiting, seizures, coma) is a medical emergency that requires prompt intervention, regardless of whether the development is acute or chronic. In addition to the morbidity associated with these symptoms directly, their development is indicative of increased intracranial pressure, which may result in brain herniation if the serum sodium concentration is not adequately raised, particularly in the setting of acute hyponatremia. Thus, the goal of therapy is to halt neurological injury and prevent progression. Increasing the serum sodium concentration by 4–6 mEq/L has been suggested to be sufficient to halt hyponatremia-related seizure activity and prevent impending brain herniation. This is primarily derived from a review of 13 case reports (individually published) of patients with severely symptomatic hyponatremia (initial serum sodium of 99–117 mEq/L with seizures [n=12] or known cerebral edema [n=2; 1 patient had cerebral edema and seizure activity]). Administration of intravenous hypertonic saline (i.e., 3% sodium chloride) resulted in an increase in serum sodium by 3–9 mEq/L within 0.5–4 hours. Eleven patients recovered, and only one patient developed ODS after a serum sodium rise of 6 mEq/L over 3.6 hours, but the patient recovered. An additional patient who had an overall increase in serum sodium of 31 mEq/L over 8 hours was disabled. Targeting absolute values for serum sodium correction (e.g., 8 mEq/L/day) is recommended, in contrast to hourly rates (e.g., 1–2 mEq/L/hour), which may obscure the rise needed within the first few critical hours of management.

Administration of intravenous hypertonic saline, usually 3% sodium chloride (513 mEq sodium per liter), is considered the definitive therapy for elevating serum sodium concentrations in severely symptomatic hyponatremia (Table 3.1). Unfortunately, no randomized trials have evaluated this intervention, and limited data are available to guide clinicians. In prior reviews, bolus intravenous administration of 3% sodium chloride (2 mL/kg or maximum 100 mL) administered over 10 minutes, with repeat administration twice if needed, was recommended to halt severe symptoms in patients with hyponatremia. Such recommendations are based on the assumption that in the absence of
free water loss in the urine, 1 mL/kg of 3% sodium chloride will increase serum sodium by about 1 mEq/L (e.g., if a patient weighing 70 kg receives the recommended maximum amount of 3% sodium chloride, 300 mL, serum sodium should increase by about 4 mEq/L).\textsuperscript{16} The 2014 European clinical practice guidelines for the diagnosis and treatment of hyponatremia (representing a joint effort on behalf of three European societies inclusive of intensive care, endocrinology, and nephrology) recommend a similar approach with intravenous administration of 3% sodium chloride as a 2-mL/kg bolus (maximum 150 mL) over 20 minutes, with repeat doses as needed until the symptoms improve or a rise in serum sodium of 5 mEq/L is attained, whichever comes first.\textsuperscript{26} Rapid (10–20 minutes) bolus intravenous administration of 3% sodium chloride has also been suggested for patients with acute hyponatremia and less severe symptoms (e.g., nausea, confusion, headache)\textsuperscript{25,26} in an attempt to prevent progression as well as for those who are relatively asymptomatic but have neurological or neurosurgical conditions (because of limited tolerance to changes in intracranial pressure).\textsuperscript{15} Overall, rapid bolus intravenous therapy is to provide a controlled and immediate rise in serum sodium with little risk of inadvertent overcorrection compared with administration by continuous intravenous infusion.\textsuperscript{25} In addition, it is suggested that this method can safely assist clinicians in ruling out hyponatremia as the cause for such symptoms (i.e., if symptoms do not resolve after a 4- to 6-mEq/L rise in serum sodium, hyponatremia is likely not the etiology).\textsuperscript{25,26} Clinicians should be aware that recommendations to administer 3% sodium chloride by small rapid intravenous infusions are primarily based on brief reports and consensus recommendations for the management of exercise-associated hyponatremic encephalopathy.\textsuperscript{27,28} A review of the literature did not identify any trials specifically evaluating the efficacy and safety of this approach in hospitalized patients. In a retrospective review of patients with severe hyponatremia (treated with 3% sodium chloride in conjunction with desmopressin [n=25]), use of an initial intravenous bolus of 50–100 mL was reported in five patients with “more severe symptoms,” but outcomes specifically related to the bolus intravenous
infusion (i.e., resolution of symptoms) were not provided.\textsuperscript{29} Therefore, the utility of this approach remains unknown. If clinicians choose to use rapid bolus intravenous administration of 3\% sodium chloride, serum sodium concentrations must be monitored post-administration of each dose in order to guide subsequent steps in management and avoid potential complications.

Administration of 3\% sodium chloride by continuous intravenous infusion is another option for managing symptomatic hyponatremia. Data analyses documenting the utility of this administration method are primarily based on retrospective case series, with most analyses including patients with both moderate and severe symptoms of hyponatremia.\textsuperscript{29-33} Ayus and colleagues conducted a recent, retrospective review of 64 adult patients with hyponatremia (less than 130 mEq/L) treated with a uniform protocol of 500 mL of 3\% sodium chloride administered intravenously over 6 hours (i.e., 83 mL/hour) after presentation to the emergency department with hyponatremic encephalopathy.\textsuperscript{33} Of the 64 patients, 46 had severe symptoms (seizures, \(n=29\); stupor, \(n=10\); coma, \(n=5\); neurogenic pulmonary edema, \(n=2\)); specifics regarding other symptoms were not provided. The median symptom duration before treatment was 48 hours (range 4 hours to 15 days). The baseline serum sodium was 114 ± 0.8 mEq/L, which rose by about 4 mEq/L, 8 mEq/L, 10 mEq/L, and 14 mEq/L at 3 hours (mid-infusion), 12 hours (6 hours post-infusion), 24 hours (18 hours post-infusion), and 48 hours (42 hours post-infusion), respectively. Of interest, within a “few hours” of initiating 3\% sodium chloride intravenously, there was a marked improvement in 97\% of hyponatremia cases and complete neurological recovery by 48 hours. Two patients who presented with seizures had permanent neurological injury after having only a 2- and 3-mEq/L rise, respectively, in serum sodium. Five patients experienced a rise in serum sodium by 25 mEq/L or more at 48 hours, but no cases of ODS were reported. This strategy provides a relatively prompt and safe response to a 6-hour intravenous infusion of 3\% sodium chloride in most patients with hyponatremia with moderate to severe symptoms, but frequent monitoring and adjustment of therapy may be needed to promptly
identify patients needing more aggressive intervention. The only prospective trial evaluating 3% sodium chloride intravenously for the acute management of hyponatremia was conducted by Bhaskar and colleagues. A total of 58 adult patients with euvolemic hyponatremia (mean serum sodium 114 mEq/L) and moderate to severe symptoms (coma 14%) for less than 24 hours were included. The initial management protocol entailed an intravenous infusion of 3% sodium chloride 100 mL over 4 hours (i.e., 25 mL/hour) targeting a rise in serum sodium by 1 mEq/L or more post-infusion, with protocol adjustments for nonresponders. Overall, 78% of patients had a rise in serum sodium of 1 mEq/L or more post-infusion with a mean of 2 mEq/L (range 0–6 mEq/L), but 22% required an additional 100–200 mL of 3% sodium chloride administered intravenously over 1–2 hours, respectively, to attain any change in serum sodium. Symptom improvement was only reported at the 24-hour mark (in contrast to post-infusion), and patients with seizure activity were excluded from the study, thus limiting the ability to determine the efficacy of this approach in severely ill patients. Accordingly, this approach may only be suitable for patients with moderate symptoms. Overall, although 3% sodium chloride intravenously can be considered a standard of clinical care for symptomatic hyponatremia, future research is needed to determine how best to deliver such therapy. Specifically, a prospective randomized trial evaluating the safety and efficacy of intravenous bolus (i.e., over 10–20 minutes) versus rapid intravenous infusion (i.e., 500 mL over 4–6 hours) of 3% sodium chloride is needed for severely symptomatic patients.

Given that 3% sodium chloride represents the primary management strategy for severely symptomatic hyponatremia, some practical considerations deserve mentioning. First, infusion by a central venous access device is recommended to minimize the development of phlebitis because of the hypertonic nature of the solution (513 mEq of sodium per liter and 1,026 mOsm/L). In patients with severe symptoms or impending herniation, 3% sodium chloride may be administered through a large peripheral vein (i.e., antecubital) if a central venous access device is not available in order to avoid delays in administration.
A recent report did not show phlebitis or extravasation injuries with peripheral administration, yet the risk still exists. Second, serum sodium concentrations must be monitored a minimum of every 4 hours in all patients receiving 3% sodium chloride intravenously. This will help identify unforeseen elevations (or lack thereof) while treating the patient with hyponatremia, allowing prompt intervention. Finally, institution-specific policies must be present regarding the intravenous administration of 3% sodium chloride, and clinicians should investigate such details to prevent delays in the provision of care to symptomatic patients. In acute care settings such as an ICU, intravenous sodium chloride concentrations greater than 0.9% are currently listed as a high-alert medication (i.e., categorized with a heightened risk of causing significant patient harm when used in error) from the Institute of Safe Medication Practices (www.ismp.org/Tools/institutionalhighAlert.asp).

After initial stabilization of severely symptomatic patients, it is essential to differentiate acute from chronic hyponatremia because this will determine the next steps of treatment (see Table 3.2). For chronic hyponatremia, treatment guidelines recommend the following maximum limits of sodium correction: 10 mEq/L in 24 hours and 18 mEq/L in 48 hours. Some experts suggest more modest goals of a 6- to 8-mEq/L rise in serum sodium in 24 hours, 12–14 mEq/L in 48 hours, and 14–16 mEq/L in 72 hours because patients with chronic hyponatremia are considered at the highest risk of ODS with serum sodium overcorrection. Thus, depending on the serum concentration and symptoms post-initial intervention, a further rise in serum sodium may not be indicated. In patients who develop acute hyponatremia over 24–48 hours, the goal serum sodium correction should be 10 mEq/L/day or less to minimize the probability of developing ODS. In contrast, for patients who develop acute hyponatremia over “several hours,” limits on the maximum amount of sodium correction within a 24-hour period have not been determined, and in general, excessive correction is not known to be harmful (i.e., no known risk of ODS). Use of 3% sodium chloride by continuous intravenous infusion may be needed to facilitate continued sodium correction and prevent redevelopment of symptoms.
Use of other interventions in conjunction with 3% sodium chloride intravenously should be considered depending on the fluid status of the patient (e.g., loop diuretics for hypervolemic or euvoletic hyponatremia).³⁰,³⁷

Determining Intravenous Infusion Rates for Hyponatremia Correction

The Adrogue-Madias equation (equation 3.3) can be used to determine the infusion rate of 3% sodium chloride required to facilitate the desired absolute rise in serum sodium.⁴ Essentially, this equation estimates the change in serum sodium after the infusion of 1 L of any infusate. The targeted rise in serum sodium (e.g., 8 mEq/L in a 24-hour period) is then divided by the estimated change in serum sodium per liter of infusate to determine the total number of liters needed, and ultimately the infusion rate per hour.

\[
\text{Change in serum sodium (mEq/L) =} \\
\frac{\text{infusate sodium + potassium content (mEq/L)}}{\text{measured serum sodium (mEq/L)}} - \frac{\text{TBW} + 1}{\text{(equation 3.3)}}^4
\]

Infusate sodium content is as follows: 3% NaCl = 513 mEq/L, 0.9% NaCl = 154 mEq/L, 0.45% NaCl = 77 mEq/L, 0.225% NaCl = 38 mEq/L, where NaCl is sodium chloride.

In a single-center retrospective review of adult patients with hyponatremia treated with 3% sodium chloride intravenously, the observed increase in serum sodium concentration was compared with that predicted by the Adrogue-Madias formula (i.e., equation 3.3). Among 31 patients with severe hyponatremia (less than 120 mEq/L), use of the formula underestimated serum sodium correction in 74%. The average rate of serum sodium correction was 1.66 times that predicted with the formula.³¹ This implies that intravenous prescribing of 3% sodium chloride using the Adrogue-Madias formula alone can result in frequent over-correction among patients, particularly
concerning with chronic hyponatremia given a higher risk of ODS.

</tbody>
</table>

$^a$Serum sodium reduction by < 0.25 mEq/L/hr within the first 24 hours of presentation may be associated with increased 30-day mortality.\textsuperscript{56}  
ODS = osmotic demyelination syndrome.

Clinicians should note that the Adrogue-Madias formula (equation 3.3) provides only an estimate, is derived from the perspective that the body is a closed system (i.e., without losses), and does not account for other factors (i.e., water diuresis mid-infusion). Overall, it is recommended that this equation be used only in determining an initial
infusion rate. Frequent serum sodium concentration monitoring (e.g., every 2–6 hours) should ultimately guide therapy.

**Inadvertent Overcorrection of Hyponatremia**

Inadvertent overcorrection of serum sodium can occur while managing hyponatremia, and such results may confer a higher risk of ODS. Overcorrection can develop during mid-treatment for several reasons; however, the primary reason is rapid resolution of the underlying hyponatremia etiology in conjunction with inadequate serum sodium concentration monitoring. Inadvertent overcorrection of serum sodium can be managed by the provision of free water enterally, intravenous infusion of 5% dextrose in water, and/or administration of intravenous desmopressin. Commercially available sterile water for injection should not be administered intravenously because of the risk of hemolysis. Desmopressin, available as an intravenous, subcutaneous, or intranasal dosage form, is a synthetic analog of ADH that inhibits free water excretion, thereby reducing serum sodium concentrations. Using desmopressin without consulting clinicians skilled in using it is not recommended because there is a potential for redevelopment of hyponatremia and associated neurological sequelae.

**Addressing the Underlying Etiology of Hyponatremia**

Determining the underlying etiology for hyponatremia is of vital importance for instituting methods to elevate the serum sodium concentration (i.e., aside from 3% sodium chloride). As mentioned previously, this requires examining the patient’s fluid status in conjunction with measuring serum osmolality, as well as urine sodium and osmolality (see Figure 3.1). Included in the following text are general considerations regarding the management of hypovolemic, euvolemic, and hypervolemic hyponatremia.

Proper management of hypovolemic hypotonic hyponatremia depends on whether the insult is caused by extrarenal or renal sodium losses. In the setting of extrarenal sodium loss (e.g., NG tube output, diarrhea), intravenous 0.9% sodium chloride (with or without potassium
chloride) should be administered to replace both sodium and fluid losses. Hypotonic fluids (e.g., 0.45% sodium chloride) should be avoided because this may worsen hyponatremia. In the absence of other concomitant factors, the specific infusion rate should be dictated by the volume lost and maintenance fluid requirements. In the setting of acute hypovolemia causing hemodynamic compromise, bolus and/or aggressive intravenous infusion rates are needed immediately. Hyponatremia should resolve with proper intravenous fluid supplementation and/or after resolution of the underlying insult (i.e., removal of the NG tube and resolution of diarrhea). In the setting of renal sodium loss, intravenous 0.9% sodium chloride should be administered with attention focused on the workup and treatment of the underlying etiology. For example, if adrenal insufficiency is identified, management should focus on glucocorticoid and mineralocorticoid supplementation. In cerebral salt wasting, intravenous fluid supplementation with 0.9% sodium chloride is typically sufficient until spontaneous resolution occurs, usually within 2–3 weeks of cerebral injury.\textsuperscript{38}

Euvolemic hypotonic hyponatremia is most often associated with SIADH,\textsuperscript{2} and in fact, SIADH is the most common cause of hyponatremia.\textsuperscript{37} A complete discussion of causes of SIADH (or syndrome of inappropriate antidiuresis) can be found elsewhere.\textsuperscript{37} Particularly of concern in critically ill patients is the potential for transient development of SIADH postoperatively,\textsuperscript{5,6} in response to pain,\textsuperscript{4} in conjunction with pneumonia,\textsuperscript{39} or secondary to neurological insult such as subarachnoid hemorrhage.\textsuperscript{40} Free water restriction is the mainstay of therapy for managing mild symptomatic hyponatremia associated with SIADH.\textsuperscript{4} Unfortunately, enteral free water restriction may be of little utility in critically ill patients because this population is often unable to drink by mouth. However, in patients receiving enteral nutrition and/or medications by enteral tube, consideration should be given to reducing the volume of free water flushes to the minimum required to prevent enteral tube occlusion.\textsuperscript{41} Intravenous fluid should be restricted by discontinuing all hypotonic fluids (e.g., 0.45% sodium chloride or 5% dextrose in water by maintenance intravenous fluids or
intravenous medication diluents) and replacing them with 0.9% sodium chloride, if feasible or compatible. This will likely be insufficient to fully correct hyponatremia associated with SIADH, and other therapies may be necessary such as loop diuretics, oral or enteral sodium chloride tablets (i.e., salt tablets), and/or demeclocycline. With respect to oral sodium chloride, each 1 g tablet contains about 18 mEq of sodium and 18 mEq of chloride. The intent behind sodium chloride tablet administration is to increase urine osmolality, helping create an osmolar gradient within the renal tubules to counteract the effect of elevated ADH concentrations and allow greater free water excretion.\(^2\)

Unfortunately, sodium chloride tablet administration is limited by the need for enteral access and the risk of adverse sequelae from sodium loading, including pulmonary edema. Demeclocycline is a tetracycline antibiotic that blocks ADH activity at the renal tubules and facilitates free water excretion. In addition to requiring enteral access, this agent has a delayed onset of action (3–6 days) and should be avoided in the setting of renal and/or hepatic impairment (common complications of critical illness).\(^1,\(^2\)\) In light of this information, clinicians are often left with loop diuretics as the only viable treatment option for managing SIADH in critically ill patients (in addition to intravenous fluid restriction). Diuresis with loop diuretics is typically equivalent to 0.45% sodium chloride\(^1\); hence, more free water than sodium is excreted, helping raise serum sodium concentrations.

Management of hypervolemic hypotonic hyponatremia targets the elevated ECF volume characteristic of disease states commonly associated with this condition (e.g., heart failure, cirrhosis, nephrotic syndrome). Disorders of the cardiovascular, renal, and hepatic systems are common in critically ill patients, and as such, hypervolemic hyponatremia should be of concern. Essentially, the goals are to achieve a negative fluid balance (by diuresis) and to minimize sodium intake. To manage this type of hyponatremia, the clinician must focus on improving the status of the underlying comorbidity. For example, in the setting of heart failure–induced hyponatremia, loop diuretic therapy is often escalated to promote aggressive diuresis. However, this is often a temporary measure because improvement in cardiac
contractility is needed in order to avoid further release in ADH and activation of the renin-angiotensinaldosterone system in response to a decreased effective circulating volume. Thus, agents such as angiotensin-converting enzyme inhibitors or angiotensin receptor blockers can be implemented, if feasible. Cirrhosis is another condition marked by the non-osmotic release of ADH in response to decreased effective circulating volume.

Vasopressin Receptor Antagonists in Hyponatremia

Vasopressin receptor antagonists, also known as aquaretics, result in increased electrolyte-free water excretion by competitive antagonism of ADH at $V_2$ receptors on the renal tubule collecting ducts. Currently, two agents are U.S. Food and Drug Administration (FDA) approved, conivaptan and tolvaptan, and both are indicated for euvolemic and/or hypervolemic hyponatremia. Conivaptan is only available as an intravenous formulation, and tolvaptan is only available as an oral tablet. Neither agent has proven to provide symptomatic relief to patients with acute hyponatremia.

Limited data exist with use of these agents in the management of acute hyponatremia in critically ill patients. Only one publication documenting two case reports of tolvaptan use in critically ill patients with euvolemic hypotonic hyponatremia from SIADH is available. With respect to conivaptan, two small pilot trials of neuro-ICU patients have been published (n=19 and n=6). Although the second trial was terminated early because of difficulties with enrollment, both studies showed conivaptan’s ability to raise serum sodium concentrations in neuro-ICU patients, providing merit for a larger, randomized controlled trial. Overall, the paucity of data with use of aquaretics in the critically ill population is not of great concern given similar deficits of well-designed controlled trials with the other interventions mentioned previously. However, given the lack of clinical symptomatic hyponatremia experience in the ICU, inability to titrate, and highly dynamic nature of critically ill patients, the role of aquaretics in the critically ill population remains to be determined.
HYPERNATREMIA

Hypernatremia is defined as a serum sodium concentration greater than 145 mEq/L. Given that sodium is a functionally impermeable solute, hypernatremia always denotes a hypertonic state, representing a deficit in TBW in relation to total body sodium\textsuperscript{47,48} In most cases, hypernatremia is iatrogenic, developing during the hospital or ICU stay\textsuperscript{11,49} The published incidence varies in the literature depending on the patient population studied (e.g., medical vs. surgical ICU) and the serum sodium diagnostic threshold (i.e., greater than 145 vs. greater than 150 mEq/L). Reports show an incidence of ICU-acquired hypernatremia of 4%–11%, with one evaluation in a mixed ICU population showing an incidence of 26\%.\textsuperscript{48} Critically ill patients who are unconscious or have an altered mental status as well as those who are intubated or receiving non-invasive mechanical ventilation are considered at highest risk of hypernatremia. In such scenarios, patients cannot regulate their own fluid intake and are completely reliant on the medical team to ensure adequate fluid provision while avoiding excessive sodium administration. Overall, ICU-acquired hypernatremia (i.e., development during ICU stay) has been proposed to be indicative of poor quality care\textsuperscript{50}.

Pathophysiology and Classification

A combination of net water loss and net sodium gain is often the driving force for hypernatremia in the critically ill population\textsuperscript{48,51} Free water loss can occur by extrarenal or renal mechanisms. Extrarenal water loss contributes to the development of ICU-acquired hypernatremia in more than 50\% of patients, primarily by way of fever\textsuperscript{51} Insensible losses, typically 10 mL/kg/day, should be considered when evaluating fluid balance\textsuperscript{52} In addition, with each 1 degree increase in temperature above 37°C, insensible losses increase by 25\% (i.e., 2.5 mL/kg/day).\textsuperscript{52} Other sources of extrarenal loss include, but are not limited to, diarrhea or ostomy output (i.e., ileostomy or colostomy), NG tube output, vomiting, surgical drain output, and losses by wounds/wound management devices. Although output is difficult to ascertain at times,
clinicians should measure it from such sources in order to best assess
daily fluid balance. Potential causes of renal free water loss in the
critically ill population include osmotic diuresis (e.g., from
hyperglycemia, protein supplementation, or mannitol), loop diuretic
administration (i.e., diuresis approximates 0.45% sodium chloride), and
diabetes insipidus (central or nephrogenic).

Sodium gain (i.e., a positive solute balance) is seldom the sole
cause of hypernatremia in the critically ill population, but it often plays a
role because of the frequent administration of sodium-containing
fluids. For example, 0.9% sodium chloride is often considered the
standard for fluid resuscitation, such as in patients with sepsis. However,
given that the sodium content (154 mEq/L) exceeds the
sodium concentration of the ECF (135–145 mEq/L), hypernatremia
may develop with continued or excessive administration, particularly in
the setting of extrarenal and/or renal water losses. In addition, 0.9%
sodium chloride is commonly used as the diluent for medications
administered by intravenous piggyback, the impact of which varies
depending on the total fluid intake per day attributable to such
medications. Intravenous push administration of sodium bicarbonate
8.4% (i.e., 1,000 mEq of sodium per liter) for correction of acidosis
may also contribute to the development of hypernatremia in the
critically ill population. Sodium is also a structural component of many
antimicrobial agents, an often overlooked but important source of
intake. Finally, the sodium content of enteral and parenteral nutrition
should be considered. Determining daily sodium balance is not feasible
because of the inability to determine sodium loss (e.g., by stool, urine,
and other sources); however, clinicians should remain cognizant of the
many common avenues by which sodium is both intentionally and
unintentionally provided to critically ill patients.

Given the fluid status of the patient, hypernatremia may be classified
as hypovolemic, hypervolemic, or euvoelemic hypernatremia, which also
provides insight into the potential etiology. Hypovolemic
hypernatremia is marked by a decrease in total body sodium, but an
even greater decrease in TBW, giving rise to hypernatremia. This is
often a result of fluid losses by the gastrointestinal (GI) tract, excessive
diuresis with loop diuretics, or insensible losses by the skin and lungs. Hypervolemic hypernatremia is marked by an increase in TBW, but an even greater increase in total body sodium. This is associated with excessive sodium supplementation (i.e., hypertonic saline or sodium bicarbonate) and/or hyperaldosteronism/corticosteroid supplementation. Euvolemic hypernatremia is marked by a loss of water with a relatively stable total body sodium content. In patients who have access to free water, euvolemic hypernatremia can be seen with diabetes insipidus. In critically ill patients who often lack access to free water, diabetes insipidus will likely manifest as hypovolemic hypernatremia. Many conditions can lead to central diabetes insipidus, including, but not limited to, neurological trauma, neurosurgical intervention, and infections (e.g., meningitis) or malignancies of the CNS. Nephrogenic diabetes insipidus can be associated with several ICU medications, including aminoglycosides, foscarnet, and amphotericin B.  

**Clinical Manifestations**

Clinical manifestations directly related to hypernatremia primarily involve the CNS. The development of hypernatremia results in the movement of free water from within brain cells to the extracellular space, leading to brain cell shrinkage. Brain cell shrinkage can lead to vascular rupture, hemorrhage, ODS, and potentially permanent neurological damage or death in severe cases. During rapid adaptation, brain cell volume is partly restored by the movement of electrolytes intracellularly; however, normalization of brain volume does not occur rapidly because the movement of organic osmolytes intracellularly takes several days (essentially, the adaptive process for hypernatremia is the opposite of that for hyponatremia). In general, patients who have a rapid rise (i.e., within hours) or large absolute rise in serum sodium are at high risk of developing severe neurological symptoms. In addition to neurological manifestations, hypernatremia has been associated with muscle weakness or cramps, rhabdomyolysis, impaired gluconeogenesis, impaired glucose use,
impaired lactate clearance, and decreased left ventricular contractility.\textsuperscript{48}

**Morbidity and Mortality**

Several retrospective studies evaluating the incidence of ICU-acquired hypernatremia have shown significantly longer ICU lengths of stay and higher mortality rates among patients who developed hypernatremia than among those who did not.\textsuperscript{48} In the retrospective review of more than 13,000 patients included in the EPIC II trial (mentioned earlier in the Hyponatremia section), a significantly increased risk of death was seen among all patients with hypernatremia, which increased in a stepwise fashion as the degree of hypernatremia progressed from mild (146–150 mEq/L; OR 1.97 [95% CI 1.74–2.23]) to moderate (151–155 mEq/L; OR 2.03 [95% CI 1.60–2.57]) to severe (greater than 155 mEq/L; OR 2.62 [95% CI, 1.90–3.61]). Of interest, these findings were primarily driven by patients who were already in the ICU at the time of hypernatremia diagnosis in contrast to those with hypernatremia at the time of admission.\textsuperscript{11} Given the retrospective nature of this information, causality cannot be confirmed between hypernatremia, timing of hypernatremia development, and mortality; nevertheless, the potential association should be of great concern for critical care clinicians.

**Management**

In general, the correction rate for hypernatremia depends on the presence or risk of severe neurological symptoms and the duration over which hypernatremia developed. Unfortunately, there are no prospective trials comparing treatment options or rate of correction for hypernatremia. As a result, treatment recommendations are primarily based on retrospective studies and expert opinion.

Patients who develop acute hypernatremia (i.e., within 48 hours or less) are at a higher risk of developing severe neurological symptoms, such as seizures, coma, and intracranial hemorrhage, if not already present.\textsuperscript{16,48} This is particularly true for hypernatremia that develops
over minutes to hours, such as in the case of salt poisoning or inadvertent administration of hypertonic saline.\textsuperscript{16} With acute hypernatremia, excessive correction of serum sodium is not known to be harmful (i.e., minimal to no risk of cerebral edema) because of insufficient time for the brain to adapt to the hypertonic state.\textsuperscript{16,48} As such, it is recommended to correct serum sodium at a rate of 2–3 mEq/L/hour until a serum sodium of 145 mEq/L is attained; then treatment should stop.\textsuperscript{16} Other experts recommend a more modest correction rate of 1 mEq/L/hour.\textsuperscript{47} For patients with chronic hypernatremia or hypernatremia of unknown duration, particularly in the absence of severe neurological symptoms, it is recommended to lower the serum by 0.5 mEq/L/hour or less.\textsuperscript{16,47,48} In addition, the total daily correction should be limited to 8–10 mEq/L/day.\textsuperscript{47,48} This is because brain cells have already adapted to the hypernatremic state, and cerebral edema may develop with rapid serum sodium correction.

A single-center, retrospective study evaluated serum sodium correction rates and mortality in 117 adult patients with hypernatremia (serum sodium greater than 155 mEq/L).\textsuperscript{56} Overall, the mean baseline serum sodium was 159 mEq/L; 20% of patients had acute and 80% had chronic (or unknown duration) hypernatremia, and 30% were admitted to the ICU. Minimal information was provided regarding symptomatology, only mentioning that 49% had impaired neurological status, and there was no standardized protocol at the institution for hypernatremia correction (i.e., according to physician discretion). The mean serum sodium correction rate was 0.15 $\pm$ 0.3 mEq/L/hour and 0.13 $\pm$ 0.1 mEq/L/hour within 24 and 72 hours, respectively. Multivariate analysis showed a significantly increased risk of 30-day mortality among patients with a serum sodium correction of less than 0.25 mEq/L/hour in the first 24 hours. The 30-day mortality rate was 46% (36 of 78) with a serum sodium correction of less than 0.25 mEq/L/hour compared with 18% (7 of 39) among those with a serum sodium correction of 0.25 mEq/L/hour or more ($p=0.0029$). In patients with acute hypernatremia, the overall rate of serum sodium correction was faster (0.36 $\pm$ 0.48 mEq/L/hour vs. 0.09 $\pm$ 0.21 mEq/L/hour) and mortality was lower (21% vs. 41%; $p=0.0962$) than in those with
chronic hypernatremia. This study suggests that overly conservative serum sodium correction within 72 hours of presentation may be detrimental in patients with chronic hypernatremia. Overall, evaluation of serum sodium correction rates and correlation with outcomes in both acute and chronic hypernatremia deserve prospective evaluation.

Fluid administration is the cornerstone of therapy for hypernatremia. The previously recommended corrections in serum sodium for both acute and chronic hypernatremia can be accomplished by intravenous administration of 5% dextrose in water (emergent dialysis can also be considered, depending on the clinical presentation of the patient). The initial intravenous infusion rate for 5% dextrose in water can be determined using the Adrogue-Madias formula (equation 3.3) provided earlier in this chapter; however, the intravenous infusion rate should be adjusted according to serial sodium measurements (e.g., every 2–6 hours). In uncontrolled hyperglycemia, 0.45% sodium chloride can be used, but concomitant use of loop diuretics should be considered to induce natriuresis. Use of 0.9% sodium chloride or other isotonic solutions (e.g., Ringer lactate) is not recommended except in hemodynamic instability.

Once symptoms are controlled, the route of fluid administration can be changed to enteral, if feasible (i.e., orally or per feeding tube). If the enteral route is not feasible, continuation of 5% dextrose in water or use of 0.45% sodium chloride is appropriate. At this time, clinicians should also focus on determining the underlying etiology of hypernatremia (e.g., excessive insensible losses, overuse of loop diuretics, diabetes insipidus) and intervene accordingly. In addition, sources of sodium intake should be minimized.

POTASSIUM

Potassium is the most abundant intracellular cation in the body, with 98% of total body stores located in the intracellular space and only 2% in the extracellular space. Skeletal muscle houses most intracellular potassium (about 75%), with the remaining potassium located within the liver and red blood cells (RBCs). The sodium-potassium adenosine
triphosphatase (Na-K-ATPase) pump regulates potassium’s distribution between the ICF and the ECF by pumping potassium inside cells in exchange for sodium, maintaining ECF (i.e., serum) potassium concentrations within a normal range of 3.5–5 mEq/L in drastic contrast to an ICF potassium concentration of about 150 mEq/L. Although potassium plays several vital roles within the body (e.g., protein and glycogen synthesis), the function of most concern for critical care clinicians is maintenance of cardiac muscle resting membrane potential. Variations in serum potassium concentrations resulting in either hyperkalemia or hypokalemia can result in significant and life-threatening arrhythmias.

Potassium homeostasis is mediated by several key factors, most importantly aldosterone, insulin, and catecholamines, and is highly dependent on renal function. Around 90% of potassium excretion occurs by renal elimination (with the remaining 10% from GI loss by feces), and aldosterone is the primary mediator for this process. A feedback loop exists whereby aldosterone production is stimulated, and thereby, renal excretion of potassium is increased in the presence of hyperkalemia and suppressed by hypokalemia. As such, aldosterone is the main regulator of total body stores of potassium. Insulin is the most important mediator of the transcellular gradient of potassium, facilitating the movement of potassium intracellularly by stimulation of the Na-K-ATPase pump. Similar to aldosterone, a feedback loops exist for insulin release. Given the heightened focus on glycemic control in the critically ill population, many ICU patients currently receive exogenous intravenous insulin infusions. In addition to facilitating the cellular uptake of potassium, a prospective cohort involving 178 surgical ICU patients showed that intravenous insulin administration is independently and positively associated with renal potassium excretion ($r^2 = 0.52$, $p<0.001$). Catecholamines lower serum potassium by stimulating the Na-K-ATPase pump, as well as promoting glycogenolysis and subsequent endogenous insulin release. In addition to hormonal mediation, serum potassium concentrations are affected by acute acid-base disorders. Overall, acidosis results in an increase in serum potassium, whereas alkalosis results in a decrease.
Some experts report that a 0.1-unit change in serum pH results in a change in serum potassium by about 0.6 mEq/L in the opposite direction; however, the magnitude of change in serum potassium appears to vary depending on the type of acid-base disorder and cannot reliably be predicted by this generalization.\textsuperscript{62}

The primary route of potassium intake is by the diet, which in critically ill patients is often administered as enteral or parenteral nutrition. The recommended dietary allowance (RDA) of potassium is about 50 mEq/day.\textsuperscript{63} Accordingly, adult enteral nutrition formulas typically contain 40–60 mEq/L of potassium in an attempt to meet the RDA, unless specifically formulated for patients with chronic kidney disease (e.g., Novasource Renal, 24 mEq/L). Potassium supplementation may be also administered through maintenance intravenous fluids. Of note, hypokalemia can be sustained with inadequate potassium supplementation and depletion of total body stores regardless of appropriate hormonal feedback and renal function; however, hyperkalemia typically resolves quickly unless one or more regulatory mechanisms are impaired.\textsuperscript{58}

**HYPOKALEMIA**

Hypokalemia is defined as a serum potassium less than 3.5 mEq/L, with severe hypokalemia typically marked by a serum potassium less than 2.5 mEq/L.\textsuperscript{59} Few studies have evaluated the prevalence of hypokalemia in the critically ill population. A single-center investigation of more than 10,000 ICU patients revealed about a 19% incidence of mild hypokalemia (3–3.49 mEq/L) and 3%–4% of severe hypokalemia.\textsuperscript{64}

**Pathophysiology**

Hypokalemia can be the result of abnormal losses of potassium, imbalance of the transcellular gradient by intracellular shifting of potassium, inadequate intake or supplementation, or a combination of these three mechanisms.\textsuperscript{58,59} In most cases, hypokalemia is a result of
abnormal losses of potassium, and diuretics (loop and/or thiazide diuretics) are the primary culprit.\textsuperscript{58,63} Abnormal losses by the GI tract should also be considered from the patient’s history. Factors associated with the development of hypokalemia are listed in Table 3.3.\textsuperscript{58,59}

**Clinical Manifestations**

Clinical manifestations of hypokalemia vary widely among patients and are primarily neuromuscular, GI, or cardiac related. Neuromuscular changes are often considered mild or nonspecific and include cramping, myalgia, and weakness. Even if these manifestations are present, critically ill patients are often unable to communicate such symptoms, which often go unnoticed until attempts are made to ambulate the patient. Severe neuromuscular symptoms, such as rhabdomyolysis and paralysis, may occur at serum potassium concentrations of less than 2.5 mEq/L and 2 mEq/L, respectively. Hypokalemia may also manifest as constipation or development of an ileus.\textsuperscript{58} Cardiac abnormalities represent a primary concern for clinicians but are considered unusual in the absence of underlying heart disease (e.g., heart failure, left ventricular hypertrophy, or cardiac ischemia).\textsuperscript{58,63} Electrocardiogram (ECG) changes may include flattening or inversion of the T wave, ST-segment depression, or prominent U waves.\textsuperscript{63} Because of alterations in the resting membrane potential of cardiac cells, hypokalemia can trigger arrhythmias such as heart block, atrial flutter or fibrillation, ventricular tachycardia, ventricular fibrillation, or torsades de pointes. In addition, the risk of hypokalemia-induced arrhythmia may be increased in the setting of digoxin toxicity.\textsuperscript{63}

**Morbidity and Mortality**

A prospective, single-center observational trial (n=60) of patients with acute myocardial infarction (AMI) showed an inverse relationship with serum potassium and the development of ventricular tachycardia. The lowest probability for ventricular tachycardia was seen with serum
potassium concentrations of 4–5 mEq/L.\textsuperscript{65} A subsequent, larger prospective observational study (n=482) of patients with AMI showed a significantly lower mean serum potassium concentration among 17 patients who developed ventricular fibrillation compared with 417 who did not (3.58 vs. 3.89 mEq/L, p<0.05).\textsuperscript{66} These studies together with others led to guideline recommendations to maintain a serum potassium concentration of at least 4 mEq/L (i.e., 4–5 mEq/L) in patients with a history of cardiac arrhythmias, hypertension, heart failure, or coronary ischemia.\textsuperscript{63} The association of serum potassium concentrations with the development of arrhythmias, as well as the incidence of mortality, has been revisited since these prior recommendations were published. In 2012, a retrospective cohort study of 38,689 patients with biomarker-confirmed AMI across 67 hospitals was published.\textsuperscript{67} Overall, a U-shaped relationship between mean post-admission serum potassium and in-hospital mortality was identified. A 4.8% and 5% incidence of death was observed among patients in the 3.5 to less than 4 mEq/L and 4 to less than 4.5 mEq/L serum potassium groups, respectively; however, mortality significantly increased in the presence of progressive hypokalemia and hyperkalemia. Of interest, the incidence of ventricular fibrillation was relatively similar among patients with a serum potassium concentration of 3 mEq/L to less than 4.9 mEq/L.\textsuperscript{67} This study suggests that maintaining serum potassium concentrations of 3.5–4.5 mEq/L may be sufficient in patients with AMI. Similarly, a minimum serum potassium threshold of 3.5 mEq/L has also been suggested to be sufficient to prevent peri- and intraoperative arrhythmias, as well as postoperative atrial fibrillation or flutter in patients undergoing coronary artery bypass grafting.\textsuperscript{68}

• GI
  ○ Vomiting, NG tube drainage
  ○ Diarrhea
  ○ High-output ileostomy or colostomy
  ○ Fistulas (e.g., enterocutaneous)
  ○ Medication-induced fecal elimination: sodium polystyrene sulfonate or sorbitol-containing enteral medications

• Renal
  ○ Loop diuretics
  ○ Thiazide diuretics
  ○ Amphotericin B
  ○ Fludrocortisone > hydrocortisone
  ○ Hypomagnesemia
  ○ Renal tubular damage (e.g., cisplatin)
  ○ Type 1 renal tubular acidosis

**HYPERkalemia**

**Pseudohyperkalemia**
- Extravascular hemolysis (i.e., inappropriate handling of laboratory specimen)

**Impaired Renal Elimination**
- Renal failure (chronic > acute)
- Adrenal insufficiency/hypoaldosteronism
- Aldosterone blockade/reduced synthesis
  ○ ACE inhibitors
  ○ Angiotensin receptor blockers
  ○ Spironolactone, eplerenone
  ○ Heparin
  ○ NSAIDs (also reduce GFR)
- Other medications
  ○ Potassium-sparing diuretics
  ○ Trimethoprim
  ○ Tacrolimus
  ○ Cyclosporine

**Metabolic or respiratory alkalosis**
- Sodium bicarbonate
- Insulin
- Nebulized β<sub>2</sub>-agonists (e.g., albuterol, levalbuterol)
- Catecholamines (e.g., norepinephrine)
- Theophylline
- Refeeding syndrome

**Inadequate Supplementation**
- Prolonged NPO or potassium-free IV fluids

**Extracellular Shift (ICF → ECF)**
- Metabolic or respiratory acidosis
- Cell lysis
  ○ Tumor lysis syndrome
  ○ Rhabdomyolysis
- Insulin deficiency/resistance (e.g., diabetes mellitus)
- Medications
  ○ β<sub>2</sub>-Antagonists
  ○ Succinylcholine
  ○ Digoxin

**Increased Intake/Supplementation**
- Iatrogenic (e.g., potassium-containing IV fluids)
- Nonadherence to diet or potassium salt substitutes in chronic kidney disease
The ideal serum potassium concentration for “critically ill” patients in general remains a conundrum, given the variety of patients cared for in the ICU. Recently, Hessels and colleagues evaluated the relationship between serum potassium, concentration variability, and outcomes among 10,451 adult ICU patients in a single-center, retrospective, observational cohort study. The study population consisted of predominantly surgical (73%) as well as medical (27%) ICU patients with a median Acute Physiology and Chronic Health Evaluation (APACHE) II score of 16, a 33% incidence of acute kidney injury, and mean serum potassium concentrations of 4.1 mEq/L and 4.2 mEq/L on admission and during their ICU stay, respectively. A U-shaped relationship between serum potassium concentrations and in-hospital mortality was identified (regardless of whether serum potassium on ICU day 1 or throughout the ICU stay was evaluated), with the lowest incidence of death among patients with a serum potassium concentration of 3.5–5 mEq/L. In addition, greater variability in serum potassium concentrations was independently associated with in-hospital mortality, even for patients with a serum potassium concentration of 3.5–5 mEq/L. Overall, potassium derangements (hypo- or hyperkalemia) and potassium variability remained independently associated with in-hospital mortality when controlling for APACHE II, presence of acute kidney injury, and other confounders. This publication suggests that a serum potassium concentration of 3.5–5 mEq/L is safe for most critically ill patients.

Management

For the treatment of hypokalemia, potassium supplementation may be administered orally or parenterally. Unfortunately, there is no one-size-fits-all approach, and the route of administration should be influenced
by the urgency of the situation (i.e., presence of symptoms, degree of hypokalemia) and the feasibility (i.e., presence of enteral feeding tube or central vs. peripheral venous access). Overall, enteral potassium replacement is recommended in critically ill patients who are asymptomatic (both clinically and by ECG), have a serum potassium concentration of 3 mEq/L or more, and have shown tolerance to other enterally administered substances (e.g., enteral nutrition or medications). Some of the available enteral potassium replacement products and specific considerations with such therapies are listed in Table 3.4. Various potassium salts are available for enteral administration including, but not limited to, chloride, bicarbonate, citrate, gluco-nate, and phosphate. Potassium chloride should be the standard potassium salt used for supplementation in most cases. If hypokalemia is caused by loop or thiazide diuretic use, concomitant use of a potassium-sparing diuretic (e.g., triamterene) or spironolactone can be considered. Serum potassium concentrations should be reevaluated daily in patients receiving oral or enteral supplementation.

Intravenous administration of potassium may be required in critically ill patients because of the lack of enteral access or patient intolerance to enteral potassium or for acute treatment of symptomatic patients. Unfortunately, recommendations vary regarding the specifics of intravenous potassium therapy, including maximum concentrations for peripheral versus central venous access device administration and maximum infusion rates. In 1990, Kruse et al. published a retrospective trial including 190 medical ICU patients who received a total of 1,351 potassium chloride intravenous infusions. A severity of illness score was not provided, but 61% of patients had respiratory failure, 42% sepsis, and 11% oliguric renal failure. Potassium supplementation consisted of 20 mEq of potassium chloride in 100 mL of 0.9% sodium chloride (200 mEq/L) administered intravenously over 1 hour through a central vein (77%) or peripheral vein (23%), with most patients receiving two or three consecutive doses (range of one to eight doses). Overall, the average change in serum potassium 1 hour post-infusion per 20 mEq administered intravenously was 0.25 mEq/L. The mean change in serum potassium per amount of potassium received is
depicted in Figure 3.2. Phlebitis and/or pain during the intravenous infusion occurred in 2.6% of cases of peripheral administration; however, this could be underreported because of limitations in the ability of patients to communicate (particularly if comatose or mechanically ventilated) and the retrospective study design. There were no instances of ventricular arrhythmias or cardiac arrest. Kruse and colleagues conducted a smaller, single-center prospective study using the same intravenous potassium chloride regimen in 40 ICU patients with a baseline serum potassium of 2.9 mEq/L (central venous access device administration in 65% of patients). In this trial, the mean change in serum potassium 1 hour post-infusion per 20 mEq administered intravenously was also 0.25 ± 0.08 mEq/L. Continuous ECG monitoring revealed a significant reduction in the incidence of premature ventricular contractions during potassium infusion. Hamill and colleagues conducted a prospective cohort study evaluating potassium chloride 20 mEq, 30 mEq, or 40 mEq in 100 mL 0.9% sodium chloride administered intravenously over 1 hour (maximum concentration 400 mEq/L; maximum infusion rate 40 mEq/hour). The small sample size (n=48) in the context of a three-arm analysis (i.e., 20-, 30-, and 40-mEq doses), subgrouping of each study group into those with and without an elevated serum creatinine, and significant variations in pretreatment serum potassium concentrations limit the ability to analyze the effects of each intervention. Collectively, the literature supports a change in serum potassium of about 0.1 mEq/L for each 10 mEq of potassium chloride intravenously administered, as well as the safety of an infusion rate up to 40 mEq/hour with concentrations of 200–400 mEq/L by a central venous access device. Unfortunately, because of low patient numbers, recommendations cannot be provided regarding potassium concentrations and maximum infusion rates by peripheral administration in the critically ill population.

Table 3.5 provides an overview of the specifics regarding intravenous potassium administration as derived from available literature. In addition, all critically ill patients with a serum potassium below 3 mEq/L, regardless of symptom presence or absence, should receive intravenous supplementation, given the risk of cardiac
arrhythmias. It is also recommended that serum potassium concentrations be rechecked within 2 hours after completion of each intravenous dose, with further supplementation as needed. If frequent potassium administration intravenously is required, consideration should be given to adding potassium to the maintenance intravenous fluids (i.e., to provide 20–80 mEq/day), as feasible, given the renal function and acid-base status of the patient. This may assist in preventing hypokalemia\textsuperscript{72} as well as minimize serum potassium variability and associated negative outcomes.\textsuperscript{64} In general, ECG monitoring is recommended with intravenous potassium infusion rates of greater than 10 mEq/hour or with lower infusion rates according to individual patient risk factor assessment.

\end{tabular}
\end{table}
Finally, clinicians should be cognizant that concomitant hypomagnesemia may result in refractory hypokalemia. Hypomagnesemia appears to promote renal potassium wasting as well as impair the Na-K-ATPase pump. In a single-center, prospective,
double-blind, randomized, placebo-controlled trial including 30 surgical ICU patients with hypokalemia (serum potassium less than 3.5 mEq/L), potassium retention after intravenous supplementation was significantly greater among patients maintained with a mean serum magnesium concentration of about 2.8–3 mg/dL versus about 2 mg/dL. Despite similar baseline serum potassium concentrations (3.3–3.4 mEq/L) and attainment of similar serum potassium concentrations (3.7–3.8 mEq/L) throughout the 48-hour study, patients who maintained a serum magnesium concentration of 2.8–3 mg/dL had a net potassium balance (i.e., intake minus urinary losses) of +72 mEq vs. -74 mEq (p<0.05) in the lower serum magnesium group and also required an average of about 100 mEq less potassium. These results highlight renal retention of potassium by intravenous magnesium supplementation. According to this study, it is prudent in the setting of concomitant hypokalemia and hypomagnesemia that intravenous magnesium be supplemented before intravenous potassium unless severe hypokalemia-related symptoms (i.e., cardiac arrhythmias) are present. In addition, if hypokalemia fails to resolve after conventional potassium replacement, consideration should be given to targeting a serum magnesium concentration of about 3 mg/dL with intravenous magnesium supplementation.

HYPERKALEMIA

Hyperkalemia is defined as a serum potassium concentration greater than 5 mEq/L, with greater than 6.5 mEq/L indicative of severe hyperkalemia. A large, two-center retrospective observational study involving more than 39,000 critically ill patients showed a 22% prevalence of hyperkalemia on ICU admission. A subsequent single-center investigation of 10,451 critically ill patients showed a 15% prevalence of mild hyperkalemia (5–6 mEq/L) and a 3.6% prevalence of severe hyperkalemia (greater than 6 mEq/L) during their ICU stay. Thus, hyper-kalemia appears to be a problem confronting clinicians both at the time of admission and throughout critical illness.
Pathophysiology

Hyperkalemia typically occurs in response to reduced potassium excretion, a shift from the intracellular to the extracellular space, or a combination of the two. Factors associated with the development of hyperkalemia are listed in Table 3.3. Impaired renal excretion is responsible for more than 80% of episodes of hyperkalemia,\textsuperscript{59} which should be of concern for critical care clinicians given that acute kidney injury can develop in up to 60% of critically ill patients.\textsuperscript{76}

Clinical Manifestations

Clinical manifestations of hyperkalemia are typically cardiac related and can be life threatening. An early ECG finding is peaked T waves (in
contrast to inverted T waves associated with hypokalemia). Typically, as the serum potassium concentration continues to rise, conduction delays occur, characterized by widening of the PR interval, loss of the P wave, and then widening of the QRS complex. Patients may develop atrioventricular conduction blockade and ultimately ventricular fibrillation or asystole. As such, focus should be placed on prevention of hyperkalemia and prompt intervention, should it develop.

**Morbidity and Mortality**

As mentioned earlier in this chapter, studies of both patients with AMI and critically ill patients in general showed a U-shaped relationship between serum potassium and ventricular fibrillation as well as in-hospital mortality. In the study by Hessels and colleagues, the incidence of mortality increased from about 15% with a mean ICU serum potassium concentration of 3.5–5 mEq/L to upward of about 45%, about 60%, and about 70% with mean serum potassium concentrations of 5.6–6 mEq/L, 6.1–6.5 mEq/L, and greater than 6.5 mEq/L, respectively. In addition, hyperkalemia on ICU admission has been associated with 30-day mortality. In a two-center, retrospective study of 39,705 critically ill patients (46% medical, 54% surgical) who were normokalemic (i.e., 4 mEq/L or more) on ICU admission, a statistically significant increased risk of death was identified among patients with a serum potassium concentration of 4.5 mEq/L or more compared with those with a concentration of 4–4.5 mEq/L, even after adjusting for several covariates. This was observed in each 0.5-mEq/L incremental category of serum potassium from 4.5–5 mEq/L to greater than 6.5 mEq/L (e.g., 5–5.5 mEq/L, 5.5–6 mEq/L). Although none of the previously mentioned studies can prove causality between hyperkalemia and mortality, the association is plausible.

### Management

Treatment of hyperkalemia consists of the following: provision of cardioprotection, shifting of potassium from the ECF to the ICF, and enhancing potassium excretion. In addition to these interventions, exogenous sources of potassium must be removed, and as feasible, medications that may indirectly contribute to potassium retention should be held. An overview of treatments used in the management of hyperkalemia is presented in Table 3.6.\(^{57,59,77-80}\) Patients presenting with cardiac symptoms must be treated promptly to prevent progression to a life-threatening event. No treatment algorithms for

symptomatic or asymptomatic patients with hyperkalemia have been validated in the literature, particularly in the care of critically ill patients. A suggested algorithm for the management of hyperkalemia in the critically ill population is presented in Figure 3.3. In general, asymptomatic patients whose serum potassium concentration is less than 5.5 mEq/L may need no medical intervention other than source control (i.e., remove all exogenous potassium and intervene depending on the underlying etiology, as feasible). Patients with a serum potassium concentration of 5.5–5.9 mEq/L require prompt evaluation with a 12-lead ECG. In addition to source control, at a minimum, such patients may benefit from pharmacologic therapy to eliminate excess potassium.
Symptomatic patients (i.e., those with ECG abnormalities) regardless of the degree of hyperkalemia require emergent
intervention. Intravenous calcium should be administered to stabilize the cardiac membrane (i.e., to restore resting membrane potential and thereby increase the threshold for generating a cardiac action potential). The amount of calcium necessary to achieve this goal is unknown, but use of either calcium gluconate 1–2 g intravenously or calcium chloride 1 g intravenously is acceptable. Calcium chloride may be preferred because of a theorized faster dissociation of calcium from the chloride salt and thus more immediate impact, but superiority has never been shown. Overall, calcium should be administered to all symptomatic patients with the exception of hyperkalemia in the setting of digoxin toxicity because calcium can propagate such toxicity.\textsuperscript{59} In addition, regular insulin (10 units) and dextrose (25–50 g) should be administered because this intervention has been shown to rapidly (within 15 minutes) and reliably shift potassium intracellularly (0.5- to 1.5-mEq/L reduction in serum potassium that can last 2–3 hours).\textsuperscript{77} Intravenous sodium bicarbonate (e.g., 50 mEq by intravenous push) can also cause modest intracellular shifts in potassium (about 0.5 mEq/L reduction in serum potassium), but this is only effective in the setting of a non-anion gap metabolic acidosis and should be reserved as adjunctive therapy in such cases.\textsuperscript{57,77} Granted that shifting of potassium intracellularly is a temporizing measure, interventions to eliminate excess potassium should be implemented as well, such as administration of loop diuretics (e.g., furosemide 20–40 mg intravenously). Hemodialysis is the most predictable and effective method for rapidly reducing serum potassium; however, in the absence of an existing dialysis catheter, this intervention may not be the most practical or efficient. Regardless, a nephrologist should be contacted early, should the patient not respond to pharmacologic methods.

**MAGNESIUM**

Magnesium is the second most abundant intracellular cation. Normal body stores of magnesium are 23–25 g with about 99% in the intracellular space, located predominantly in bone (50%–60%), skeletal muscle (20%–30%), and soft tissues (20%). Only about 0.3% of total
body magnesium is located in the serum. As such, normal serum magnesium concentrations range from 1.8 to 2.4 mg/dL (1.5–2 mEq/L) and are not reflective of total body stores.

Most magnesium in the ECF is in the ionized (active) form, with 20% bound to serum proteins. Results vary regarding whether total and ionized serum magnesium concentrations correlate in critically ill patients, with some studies showing a strong and others a poor correlation. There have also been investigations regarding whether ionized serum magnesium concentrations are better predictors of clinical outcomes and response to magnesium supplementation, but similarly, conflicting results exist. The magnesium tolerance test may be the most accurate method of determining magnesium deficiency; however, the requirement for “normal” renal function, influence of diuretic therapy, and cumbersome procedure lead to little utility in critically ill patients. At this time, assessment of total serum magnesium concentrations remains the most widely available and accepted method of evaluation in critically ill patients.

Magnesium is an essential cofactor in hundreds of enzymatic reactions, including the formation of ATP, replication and transcription of DNA, and translation of messenger RNA. Magnesium is essential to mitochondrial function, cell membrane function, neuromuscular transmission, parathyroid hormone (PTH) secretion, and glucose metabolism. As mentioned earlier under hypokalemia, the NaK-ATPase enzyme is dependent on magnesium for proper functioning; thus, magnesium helps regulate the transcellular gradient as well as renal excretion of potassium. Magnesium also plays a role in smooth muscle tone by regulating intra-cellular calcium concentrations. Specifically, magnesium decreases activation of inositol triphosphate, decreasing calcium release from the sarcoplasmic reticulum, and also activates calcium ATPase, facilitating the movement of calcium back into the sarcoplasmic reticulum and from the ICF to the ECF. Magnesium deficiency has been proposed to cause coronary vasospasm, hypertension, bronchial airway constriction, and seizures.

Magnesium homeostasis is regulated by the small bowel and the
Overall, 30%–50% of dietary magnesium is absorbed under normal conditions, primarily in the jejunum and ileum. Gastrointestinal absorption of magnesium is saturable and inversely proportional to intake. The kidneys play the most important role in magnesium homeostasis, with about 95% of all filtered magnesium reabsorbed into the systemic circulation. Most reabsorption occurs in the thick ascending limb of the loop of Henle (65%–75%), followed by the proximal tubule (15%–20%) and the distal tubule (5%–10%). The serum magnesium concentration is the primary regulator of magnesium reabsorption because calcium and magnesium receptors located on the capillary side of the thick ascending limb of the loop of Henle sense serum magnesium concentrations and enhance or reduce reabsorption accordingly. There are no hormonal mediators of magnesium homeostasis; thus, serum magnesium concentrations can profoundly be affected by changes in intake and/or renal function (including use of diuretics).

**HYPOMAGNESEmia**

Hypomagnesemia is defined as a serum magnesium concentration less than 1.8 mg/dL (less than 1.5 mEq/L). The incidence of hypomagnesemia on ICU admission ranges from 20% to 61%, with the large variation likely attributable to different diagnostic thresholds and patient populations. The incidence of ICU-acquired hypomagnesemia is not well reported.

**Pathophysiology**

The predominant causes of hypomagnesemia can be divided into two categories: GI and renal-related losses. The content of magnesium in upper GI fluids (i.e., stomach) is about 1 mEq/L, which is in contrast to the 15 mEq/L found in the lower intestines. Hypomagnesemia from GI loss of magnesium can be observed with frequent vomiting, high NG tube output, diarrhea (including excessive use of cathartic agents), high ileostomy or colostomy output, and enterocutaneous fistulae. Damage
to the bowel can lead to decreased magnesium absorption (i.e., increased output by feces) such as that seen with radiation enteritis, Crohn disease, or ulcerative colitis. In addition, physical manipulation of the bowel may limit the surface area for magnesium absorption, such as that seen with extensive small bowel resections.\textsuperscript{81,82}

Renal loss of magnesium in critically ill patients may often be iatrogenic and associated with medications provided to treat their acute illness. Loop diuretics are a prominent cause, given their activity at the thick ascending limb of the loop of Henle.\textsuperscript{82} Aminoglycosides, amphotericin B products, and foscarnet have been associated with renal magnesium wasting, as have cyclosporine and tacrolimus. For critically ill oncology patients, prior use of a platinum-based chemotherapeutic agent (e.g., cisplatin, carboplatin, oxaliplatin) will predictably result in renal magnesium wasting.\textsuperscript{81,82} Renal magnesium wasting can also be seen with hyperglycemia (secondary to an osmotic diuresis), in the diuretic phase of acute kidney injury, and in those with chronic alcohol abuse.\textsuperscript{81,82} Other less common causes of hypomagnesemia (e.g., hungry bone syndrome) have also been reported in the literature.\textsuperscript{81}

**Clinical Manifestations**

Hypomagnesemia can be considered an “excitatory” state, and potential clinical manifestations are listed in Table 3.7. Cardiac complications are a prominent concern for clinicians, particularly development of atrial fibrillation, supraventricular tachycardia, or ventricular arrhythmias, such as torsades de pointes.\textsuperscript{82} Electrocardiographic abnormalities that can be seen include a prolonged PR interval, widening of the QRS complex, and peaked (mild hypomagnesemia) or flattened (severe hypomagnesemia) T waves.\textsuperscript{82,83} Given that hypomagnesemia and hypokalemia often coexist,\textsuperscript{93} it is difficult to attribute such cardiac abnormalities to hypomagnesemia alone. Neuromuscular hyperexcitability, including spontaneous carpal-pedal spasms and seizures, may develop.\textsuperscript{82} Seizures should be of particular concern in patients with
hypomagnesemia and a history of epilepsy or those considered at high risk (e.g., neuro-surgical intervention, alcoholism). Refractory hypokalemia can be observed in the presence of hypomagnesemia for reasons mentioned earlier. Finally, through inhibition of PTH release and/or activity, hypomagnesemia can also contribute to the development of hypocalcemia, which may exacerbate neuromuscular excitability.\textsuperscript{82}

\textsuperscript{a}To convert magnesium in mg/dL to mEq/L, divide by 1.2.

**Morbidity and Mortality**

With respect to clinical outcomes, observational trials have shown a significantly higher mortality among patients with versus without hypomagnesemia on ICU admission.\textsuperscript{88-90,94} In addition, reports have
associated hypomagnesemia with increased ICU and hospital length of stay, lack of recovery from acute kidney injury, and lactic acidosis. Of note, in none of these reports can causality be determined.

Management

Overall, there are few data regarding the treatment of patients with severely symptomatic hypomagnesemia. Intravenous administration of magnesium is plausible for the treatment of such patients, and magnesium sulfate or chloride are the only intravenous formulations currently available in the United States. For patients with torsades de pointes, magnesium sulfate is the drug of choice according to the American Heart Association guidelines, with a recommended dose of 2 g administered by intravenous push over 1–2 minutes (with 10–20 mL of 0.9% sodium chloride flush to ensure systemic delivery). If the response is inadequate, a second intravenous bolus of 2 g can be administered within 5 minutes. This recommendation is primarily based on a case series of 12 patients with torsades de pointes successfully treated with this regimen. It is unclear whether this dosing regimen for magnesium sulfate could also be considered in patients who are hypomagnesemic presenting with other atrial or ventricular arrhythmias, as well as those with refractory status epilepticus. After the initial bolus, a continuous intravenous infusion should be provided to sustain the serum magnesium concentrations, yet data are lacking for the specifics of such therapy in these clinical scenarios. When reviewing the protocols for magnesium sulfate evaluated in clinical trials for AMI and stroke, dosages of up to 160 mEq have been infused intravenously over 24 hours and safely used in patients with a serum creatinine concentration of less than 2.3 mg/dL. Intravenous recommendations for continuous magnesium sulfate in the treatment of symptomatic patients are provided in Table 3.8. As a safety measure with such high doses, patients’ respiratory rate, deep tendon reflexes, and urine output should be monitored often. Clinicians should expect serum magnesium concentrations to be elevated during the infusion, but concentrations up to 3.5 mg/dL may be
 tolerated. After the first 24 hours of magnesium treatment, an additional 0.5 mEq/kg/day intravenously is recommended on days 2–5 to account for potential total body magnesium deficits. Magnesium replacement should be continued until hypocalcemia or hypokalemia unresponsive to conventional supplementation resolves. Administration of large doses of magnesium sulfate as described in Table 3.8 should be avoided in patients with hypotension, bradycardia, or heart block because hypermagnesemia may exacerbate these conditions.

In asymptomatic patients, magnesium supplementation is often provided in a preventive manner to maintain normal serum concentrations. As mentioned earlier, poor outcomes have been observed in patients admitted to the ICU with hypomagnesemia; however, the ability of magnesium supplementation to prevent such outcomes remains unknown, as does the ideal serum magnesium concentration in asymptomatic critically ill patients. Conventionally, many ICU clinicians target a serum magnesium concentration of about 2 mg/dL; however, no data support that this practice is more beneficial than simply maintaining normomagnesemia (i.e., 1.8 mg/dL or more). Table 3.4 lists some of the available enteral magnesium products. These products can be considered for maintenance therapy, but they often have a limited role because of their low bioavailability and potential cathartic effect. As a result, intravenous magnesium is often used. In general, for every 1 g of magnesium sulfate administered, the serum magnesium concentration is expected to increase by 0.1 mg/dL. Considerations regarding intravenous magnesium sulfate administration are provided in Table 3.5, including a recommended infusion rate. Although an infusion rate of 32 mEq/hour has been reported in the literature, using conservative infusion rates of 4–16 mEq/hour is recommended because renal elimination of magnesium is directly correlated with serum concentrations. In the presence of normal serum magnesium concentrations, renal elimination of magnesium is increased; therefore, an unnecessarily rapid rise in serum magnesium concentration may lead to a greater portion of the administered dose being eliminated by the kidneys, ultimately impairing the ability to replete total body stores. In addition, a minimum of 2 g of
intravenous magnesium sulfate is recommended in order to observe any significant change in the serum magnesium concentration. Serum magnesium concentrations should be rechecked 2 hours after completion of each intravenous infusion. If consistent replacement is needed, clinicians are encouraged to add magnesium to the patient’s maintenance intravenous fluids to avoid serum concentration oscillations (similar to that recommended for potassium).

HYPERMAGNESEMIA

Technically, hypermagnesemia is defined as a serum magnesium concentration greater than 2.4 mg/dL (2 mEq/L); however, symptoms of hypermagnesemia typically do not develop until serum concentrations reach or surpass 3.5 mg/dL.83 The incidence of hypermagnesemia on ICU admission is relatively low (5%–7%).88-90 and no data are available regarding ICU-acquired hypermagnesemia.

Hypotension is usually the first clinical manifestation of hypermagnesemia, followed by bradycardia, sedation, and hyporeflexia. If serum magnesium concentrations rise drastically (8.5 mg/dL or higher), patients can have somnolence, coma, respiratory depression, and even asystole (Table 3.7).83 In critically ill patients, hypermagnesemia can be iatrogenic (i.e., overcorrection of hypomagnesemia) or a result of acute renal failure. Other potential, less likely causes of hypermagnesemia in the critically ill population include drug induced (i.e., magnesium-containing cathartics), hypothyroidism, Addison disease, and diabetic ketoacidosis.83

Management of hypermagnesemia revolves around reversing the symptoms (if present) and lowering the serum magnesium concentration in addition to correcting the underlying etiology. In the presence of cardiac or neuromuscular symptoms, administration of 100–200 mg of intravenous elemental calcium (i.e., calcium gluconate 1–2 g or calcium chloride 500 mg to 1 g) is recommended because calcium antagonizes the activity of magnesium. In addition, cardiac support (e.g., vasopressor therapy, trans-cutaneous pacing) and/or respiratory support (e.g., endotracheal intubation) may be needed for
severe hypermagnesemia. In patients with preserved renal function, serum magnesium concentrations may be lowered using loop diuretics (e.g., furosemide 20–40 mg intravenous push) in addition to intravenous hydration with an isotonic fluid. Finally, immediate hemodialysis may be needed, particularly in patients with chronic kidney disease or those who are acutely oliguric or anuric.

*a Subsequent therapy after 2 g (16 mEq) IV push of magnesium sulfate for patients with severe symptoms.

*b To convert magnesium in mg/dL to mEq/L, divide by 1.2.

*c Based on ideal body weight and provided as a continuous infusion over 24 hr; only suggested for use in patients with urine output > 0.5 mL/kg/hr and estimated creatinine clearance > 50 mL/minute/1.73 m²; in the setting of renal insufficiency, consider 25%–50% of suggested dose and reevaluate serum magnesium concentration every 12 hr.

**PHOSPHORUS**

Phosphorus is the body’s primary intracellular anion and is present as both organic (i.e., bound) and inorganic (i.e., free) phosphate. Most intracellular phosphate consists of organic phosphate esters, including 2,3-diphosphoglycerate, adenosine, and guanosine triphosphate. Most
inorganic phosphate is contained within the ECF.\textsuperscript{104}

Phosphate is essential in the development of phospholipid cell membranes, nucleic acids, phosphoproteins, and ATP, the main energy source for most cellular functions.\textsuperscript{104} On average, the human body contains only 250 g of ATP and turns over its own body weight equivalent in ATP each day. Phosphate also regulates several enzymatic reactions, including glycolysis, ammoniagenesis, and the 1-hydroxylation of 25-hydroxyvitamin D. In addition, phosphate is required for the production of 2,3-diphosphoglycerate in RBCs, a compound necessary for proper oxygen delivery to tissues.\textsuperscript{104} Finally, phosphate serves as the primary buffer in the urine.

The normal serum phosphorus concentration in adults is 2.5–4.5 mg/dL.\textsuperscript{81,104} During the day, serum phosphorus concentrations can oscillate by as much as 2 mg/dL, reflecting acute changes in transcellular distribution secondary to carbohydrate intake and insulin secretion.\textsuperscript{104} 1,25-Dihydroxycholecalciferol (i.e., activated vitamin D) and PTH are the primary mediators of phosphorus homeostasis (Figure 3.4). Around 60\%–80\% of ingested phosphorus is absorbed in the GI tract, primarily in the jejunum, through both active and passive processes. Gastrointestinal absorption of phosphorus by active transport is directly facilitated by 1,25-dihydroxycholecalciferol and indirectly by PTH (through activation of vitamin D).\textsuperscript{104,105} Parathyroid hormone also increases serum phosphorus concentrations by stimulating the release of phosphorus from bones.\textsuperscript{105} However, PTH prevents renal tubular reabsorption of phosphorus after glomerular filtration, ultimately reducing serum phosphorus concentrations because this effect overshadows PTH-mediated GI absorption and release from bone.\textsuperscript{105}
Figure 3.4 Overview of phosphorus homeostasis.

aPTH mediated inhibition of phosphorus reabsorption by the kidneys overshadows phosphorus resorption from bone and absorption from the gastrointestinal tract, ultimately resulting in hypophosphatemia

GI = Gastrointestinal; PTH = Parathyroid hormone

HYPOPHOSPHATEMIA

Hypophosphatemia is defined as a serum phosphorus concentration less than 2.5 mg/dL, with severe hypophosphatemia characterized by a concentration of less than 1 mg/dL. The prevalence of hypophosphatemia in critically ill patients varies widely (10%–80%).106 A recent large, single-center retrospective study involving 2,730 adult critically ill patients showed a 20% prevalence of hypophosphatemia.107

Pathophysiology
Hypophosphatemia can develop as a result of decreased intake/absorption, increased renal excretion, and/or internal redistribution. Internal redistribution of phosphorus (i.e., from the ECF to the ICF) is considered the most common cause of hypophosphatemia and can be seen with hyperventilation/respiratory alkalosis, insulin secretion/provision (e.g., management of diabetic ketoacidosis), hungry bone syndrome after parathyroidectomy, and refeeding syndrome. Refeeding syndrome is typically observed when glucose (either enterally or parenterally) is provided to patients after periods of prolonged (e.g., 7–10 days) starvation or inadequate nutrition, resulting in rapid intracellular shifts of potassium, magnesium, and phosphorus. Patients who have insufficient phosphorus stores because of preexisting malnutrition, such as in those who abuse alcohol and patients with cancer cachexia, may be particularly prone to refeeding-induced hypophosphatemia. In addition, in the setting of extensive burns and prolonged hyperventilation, phosphate stores may be quickly exhausted through the building of new cells and maintenance of ATP quantities sufficient for diaphragmatic contractions. Decreased GI absorption of phosphate may occur as a result of vitamin D deficiency, excessive administration of phosphate-binding agents (e.g., sevelamer, calcium carbonate), or use of other enteral medications that inadvertently bind phosphate in the GI tract (e.g., sucralfate). Increased urinary excretion of phosphate can be seen with primary and secondary hyperparathyroidism, osmotic diuresis, volume resuscitation, and Fanconi syndrome.

Clinical Manifestations

Given the many roles of phosphate in the body, it is not surprising that hypophosphatemia can affect many organ systems. Clinical manifestations of hypophosphatemia are thought to be primarily related to the depletion of ATP (e.g., myalgia, respiratory failure, heart failure) and reduced RBC concentrations of 2,3-diphosphoglycerate (e.g., metabolic encephalopathy syndrome from tissue hypoxia). Significant neuromuscular and cardiac sequelae can be seen with
severe hypophosphatemia (i.e., less than 1 mg/dL). However, moderate hypophosphatemia (i.e., 1–2 mg/dL) can also result in significant clinical manifestations, including impaired diaphragmatic contractility, intermittent ventricular tachycardia, and insulin resistance.

### Morbidity and Mortality

Despite the wide array of organ systems affected, hypophosphatemia does not appear to be associated with an overall increased risk of mortality. In a recent single-center observational study including 2,730 adult critically ill patients (34% surgical, baseline APACHE II of 18), multivariate logistic regression failed to reveal an independent association of hypophosphatemia with ICU mortality (OR 0.86; 95% CI, 0.66–1.10) or hospital mortality (OR 0.89; 95% CI, 0.73–1.07). The lack of statistical significance was observed regardless of the hypophosphatemia threshold evaluated (1.9 or less, 1.5 or less, 1.2 or less, 0.9 or less, 0.6 mg/dL or less), although the small number of patients with a serum phosphorus concentration of 0.9 mg/dL or less (n=55) may have influenced the results for this subset. In contrast, critically ill patients undergoing intermittent hemodialysis and experiencing hypophosphatemia had an increased incidence of in-hospital and 1-year mortality, as well as prolonged dialysis dependency, delayed recovery of complete renal function, and a higher prevalence of chronic kidney disease at 1 year. Overall, the impact of hypophosphatemia on mortality in critically ill patients, irrespective of renal function, deserves evaluation in prospective trials. The potential impact of hypophosphatemia on vital organ function (e.g., reduced cardiac contractility and impaired diaphragmatic contraction) demands daily serum phosphorus evaluation and prompt supplementation in the critically ill population.

### Management

Hypophosphatemia can be corrected with oral or intravenous
phosphate supplementation. In general, oral phosphate replacement should be reserved for patients who are asymptomatic and may be considered when the serum phosphorus concentration is greater than or equal to 2 mg/dL. Some of the more commonly used enteral replacement options for phosphate are presented in Table 3.4. Clinicians must be cognizant that oral phosphate administration can result in a cathartic effect, and some preparations contain significant amounts of potassium.

Intravenous administration of phosphate is the recommended route for managing symptomatic hypophosphatemia and is typically recommended for critically ill patients with a serum phosphorus concentration less than 2 mg/dL, even in the absence of symptoms. Intravenous phosphate is available as both a sodium and potassium salt. The management of hypophosphatemia may be the most widely studied electrolyte derangement in the critically ill population other than hyponatremia. Table 3.9 provides a summary of the available data regarding intravenous phosphate replacement. Overall, studies vary widely in many respects including, but not limited to, the patient population (e.g., trauma, mixed medical-surgical), classification of hypophosphatemia, phosphate replacement regimen (e.g., fixed vs. weight-based dosing), infusion rate, and assessment of efficacy. In general, patients with renal dysfunction (e.g., urine output less than 30 mL/hour), hypo- or hypercalcemia, and conditions associated with phosphaturia (e.g., Fanconi syndrome) were excluded from most trials. When the larger and more recent trials evaluating intravenous phosphate replacement are viewed together, it appears that doses of $0.16–0.32 \text{ mmol}/\text{kg}$, $0.32–0.64 \text{ mmol}/\text{kg}$, and $0.64–1 \text{ mmol}/\text{kg}$ are required to correct mild (i.e., $2.2–2.9 \text{ mg/dL}$), moderate ($1.6–2.2 \text{ mg/dL}$), and severe ($1.5 \text{ mg/dL}$ or less) hypophosphatemia, respectively, in most critically ill patients. As shown by Brown and colleagues, it may be prudent to use the upper limit of such recommendations in trauma patients, particularly those with traumatic brain injury. The dose of intravenous phosphate should be rounded to the nearest 3-mmol interval (e.g., 21 mmol vs. 20 mmol) to ease compounding because both intravenous sodium and potassium
phosphate include 3 mmol of phosphate per milliliter. In addition, it is imperative to repeat serum phosphate concentrations 2–6 hours post-infusion and daily because serum phosphorus may undergo rapid redistribution, and additional supplementation may be necessary in the setting of a total body deficit. Serum calcium and magnesium should be monitored concurrently.

With respect to the ideal infusion rate of intravenous phosphate, a study that compared 7.5 mmol/hour with 15 mmol/hour showed a greater urinary fractional excretion of phosphorus with 15 mmol/hour and no difference in serum phosphorus concentrations between the groups at the end of infusion. This suggests that 15 mmol/hour exceeds the renal threshold for phosphorus reabsorption (and may also contribute to hyperkalemia if potassium phosphate is administered). Bech and colleagues showed impaired tubular reabsorption of phosphorus with an infusion rate of 10 mmol/hour. Accordingly, a standard infusion rate for intravenous phosphate of 7.5 mmol/hour is recommended, with a maximum of 15 mmol/hour in patients having severe symptoms (i.e., respiratory failure) for which rapid correction is needed.

<sup>14</sup> Serum phosphorus measured at 0.65 mmol/L at End of Infusion in all except 1 patient in group 2.
HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as a serum phosphorus concentration greater than 4.5 mg/dL. In one report of 2,730 critically ill patients and more than 10,000 serum phosphorus measurements, 45% of all serum phosphorus measurements were indicative of hyperphosphatemia; however, the prevalence of hyperphosphatemia in the critically ill population is not well defined. Hyperphosphatemia is predominantly an electrolyte derangement of those who are dialysis-dependent and has been associated with an increased risk of all-cause and cardiovascular mortality in this population.

Pathophysiology

Hyperphosphatemia is usually a complication of renal dysfunction in which filtration of phosphorus is impaired. This can be seen in both acute kidney injury and chronic kidney disease, often leading to the use of phosphate-binding agents in patients with dialysis dependence.
Other causes of hyperphosphatemia in the critically ill population include iatrogenic administration of large phosphate loads, cell destruction (e.g., tumor lysis syndrome, trauma, rhabdomyolysis, hemolysis), lactic or diabetic ketoacidosis, and hypoparathyroidism.\textsuperscript{81,104} Clinicians should be cognizant of the large amounts of phosphorus contained in rectal cathartic products. For example, adult phosphate cathartic enemas contain about 180 mmol per dose. Caution should be exercised with use of these products in older adults, patients with impaired renal function, and patients taking other medications that may affect renal function (e.g., ketorolac). Tumor lysis syndrome is of concern in the critically ill oncologic population, particularly those with a highly proliferative malignancy (e.g., non-Hodgkin lymphoma) or severe leukocytosis, especially in the presence of concomitant chronic kidney disease. Spontaneous or treatment-induced cell lysis will result in the release of intra-cellular phosphate stores into the ECF compartment.\textsuperscript{121,122} Cellular damage and release of intracellular phosphorus is also the pathophysiology of hyperphosphatemia in the setting of trauma, rhabdomyolysis, and hemolysis.\textsuperscript{81} Lactic and diabetic ketoacidosis can result in the shifting of phosphorus from the ICF to the ECF, raising serum phosphorus concentrations. This shift is temporary, and clinicians should be aware of the potential for hypophosphatemia after correction of the underlying acidosis.\textsuperscript{104} Finally, in the setting of hypoparathyroidism, serum phosphorus concentrations will increase primarily because of decreased renal elimination (i.e., increased renal tubular reabsorption from decreased PTH).

**Clinical Manifestations**

Serum phosphorus can complex with serum calcium, leading to the development of calcium-phosphate precipitates. These precipitates can deposit in the lungs (impairing respiratory function possibly resulting in death),\textsuperscript{123} kidneys (impairing filtration), bladder (resulting in nephrolithiasis), and/or ureters (causing obstructive uropathy). Other potential acute manifestations include nausea, vomiting, diarrhea,
lethargy, and/or seizures. Long-term complications include accumulation of calcium-phosphate precipitates in the soft tissues and vasculature of the body, as well as complications from associated hypocalcemia.\textsuperscript{104}

Management

In general, emergency treatment of hyperphosphatemia is only needed if a patient is having severe symptoms from associated hypocalcemia (e.g., tetany). In such cases, intravenous calcium gluconate or calcium chloride may be administered cautiously until symptoms resolve at the lowest possible dose of calcium. Although this increases the risk of calcium-phosphate precipitation, correction of tetany is of primary importance.\textsuperscript{104} Dialysis could be considered first to correct severe hyperphosphatemia. Continuous dialysis may be needed in cases of continued release of intracellular phosphorus from ongoing damage (e.g., tumor lysis syndrome).\textsuperscript{124} For non-emergent hyperphosphatemia, reduction in phosphate administration (e.g., phosphate-restricted diet or use of enteral nutrition appropriate for chronic kidney disease) should occur. In addition, use of phosphate-binding agents, such as calcium carbonate or sevelamer, can be considered, particularly in patients with chronic kidney disease. Chronic administration of aluminum-containing antacids to facilitate phosphate binding is not recommended because of the potential to elicit anemia, bone disease, and altered mental status from aluminum accumulation.\textsuperscript{104}

CALCIUM

Calcium is predominantly an extracellular cation, with an extracellular to intracellular gradient of about 10,000:1 mmol.\textsuperscript{125} Most (99\%) total body calcium is stored in the bones.\textsuperscript{105} In the serum, calcium circulates in three forms: ionized (50\% of total serum calcium), protein bound (40\%, predominantly to albumin), and as a complex with organic and inorganic acids, such as citrate and phosphate (about 10\%).\textsuperscript{105} Ionized calcium is the only biologically active form and has several vital roles within the
These include the propagation of neuromuscular activity, mediation of action potential in cardiac and smooth muscles, excitation/contraction coupling in skeletal muscle, regulation of endocrine and exocrine secretory functions, blood coagulation and platelet adhesion, cell membrane stability and for the structural integrity of bones. Thus, alterations in serum calcium can result in several clinical manifestations including muscle weakness, tetany, convulsions, hypotension, systolic dysfunction, and potentially cardiac arrest.

Calcium homeostasis is primarily maintained through the activity of PTH and vitamin D, with other hormones (e.g., calcitonin) playing only a minor role (Figure 3.5). In general, PTH secretion is stimulated by low serum ionized calcium concentrations and inhibited by elevated concentrations. Parathyroid hormone increases serum ionized calcium by directly stimulating the release of calcium from bone and reabsorption by the kidneys. Parathyroid hormone also stimulates 1-β-hydroxylase, the enzyme responsible for the rate-limiting step of vitamin D activation (i.e., conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D or calcitriol). Calcitriol directly increases ionized calcium concentrations by facilitating the absorption of ingested calcium in the small intestine by active transport. Under normal conditions, 30%–35% of dietary calcium is absorbed by both passive and vitamin D–mediated active transport. As calcitriol concentrations rise with subsequent elevations in ionized calcium, PTH secretion is suppressed. Calcitonin works the opposite of PTH, impairing calcium release from bone and reabsorption in the renal tubules, ultimately decreasing serum calcium. However, endogenous production of calcitonin has little overall impact on serum calcium homeostasis because PTH activity predominates.

Reference ranges for total serum calcium and ionized calcium are 8.5–10.5 mg/dL and 1.12–1.33 mmol/L, respectively. In critically ill patients, it is recommended to evaluate ionized in contrast to total serum calcium. This recommendation is made because of the following: (1) ionized calcium is the biologically active form (as mentioned previously); (2) changes in serum albumin are commonly seen in
critically ill patients, and such changes can profoundly affect total calcium concentrations; and (3) use of equations to adjust total serum calcium for changes in serum albumin do not correlate well with measured ionized calcium. In general, as serum albumin falls, so does the measured total calcium. The modified Orrell method (equation 3.4) is commonly used for adjusting total serum calcium concentrations.\textsuperscript{126,127}

\[
\text{corrected serum calcium (mg/dL) = measured serum calcium (mg/dL) + 0.8[4 – albumin (g/dL)]}
\]

\text{(equation 3.4)}\textsuperscript{127}

Trials evaluating the utility of the modified Orrell equation against measured ionized calcium show that the formula overestimates hypercalcemia\textsuperscript{128} or normocalcemia\textsuperscript{129} and underestimates\textsuperscript{129} or fails to identify hypocalcemia.\textsuperscript{128} In a study of 100 critically ill trauma patients receiving nutrition support, 22 different formulas (7 to estimate ionized calcium and 15 to correct total calcium) were evaluated against measured ionized calcium.\textsuperscript{130} In this trial, 21\% of patients were hypocalcemic (measured ionized calcium of 1.12 mmol/L or less), and 6\% were hypercalcemic (measured ionized calcium of 1.33 mmol/L or greater). Overall, for the 22 methods, the mean sensitivity for predicting hypocalcemia was 25\%, specificity 90\%, false-positive rate 10\%, and false-negative rate 75\%; for predicting hypercalcemia, the sensitivity was 15\%, specificity 83\%, false-positive rate 17\%, and false-negative rate 85\%. Although some formulas performed better than others, none of the formulas had a sensitivity and specificity above 80\% for predicting both hypo- and hypercalcemia.\textsuperscript{130} If only a total serum calcium concentration is available, a concentration less than 7 mg/dL has been associated with a higher rate of ionized hypocalcemia, whereas concentrations of 7–7.9 mg/dL have not.\textsuperscript{131}
HYPOCALCEMIA

Hypocalcemia is defined as an ionized calcium concentration of 1.12 mmol/L or less (or total serum calcium less than 8.5 mg/dL, although this method of assessment is not recommended because of the reasons discussed previously). The incidence of hypocalcemia in the critically ill population varies widely secondary to differences in definition (i.e., use of ionized vs. total calcium, variations in threshold) and study population (e.g., trauma, surgical). Ionized hypocalcemia is reported to occur in 15%–88% of critically ill patients.125,129,131-134
Pathophysiology

The etiology of hypocalcemia in critically ill patients is likely multifactorial. Proposed factors include secondary hypoparathyroidism or relative PTH deficiency, impaired activation of vitamin D, calcium chelation, acid-base abnormalities, hyperphosphatemia, and iatrogenic causes. Patients with liver and/or renal dysfunction may be predisposed to hypocalcemia because of impaired hydroxylation of vitamin D to 25-hydroxyvitamin D and subsequently to 1,25-dihydroxyvitamin, respectively. In addition, frequent packed RBC transfusion may contribute to hypocalcemia by chelation of calcium by citrate. Citrate-mediated chelation is also of concern with continuous renal replacement therapy, necessitating frequent assessment of ionized calcium. Development of alkalosis facilitates protein binding of calcium and can therefore decrease ionized calcium concentrations. In general, for every 0.1-unit increase in serum pH above 7.4, ionized calcium is expected to decrease by about 0.05 mmol/L. In the setting of chronic kidney disease, hyperphosphatemia can cause hypocalcemia by the complexing of calcium and phosphate, as mentioned earlier. Secondary hypoparathyroidism can be seen after head and neck surgical intervention with excision or damage to the parathyroid gland (e.g., thyroidectomy). In addition, hypomagnesemia can lead to both decreased PTH secretion and PTH resistance. Hypocalcemia can also be a complication of acute pancreatitis secondary to saponification of calcium with free fatty acids. Finally, medications should also be considered in the differential diagnosis that result in unintended calcium wasting in the urine, such as foscarnet and loop diuretics, as well as therapeutic measures to treat hypercalcemia, such as calcitonin or bisphosphonates.

Clinical Manifestations

Clinical findings of hypocalcemia are associated with the neuromuscular, cardiovascular, respiratory, and central nervous systems. Some experts consider neuromuscular irritability the hallmark of hypocalcemia, manifesting as tetany (characterized by circumoral
numbness, distal extremity paresthesia, and muscle cramps). Other potential neuromuscular findings include Trousseau sign, Chvostek sign, and hyperactive reflexes. Such findings are a result of a lower resting membrane potential, allowing more frequent nerve signal generation.\textsuperscript{105} Cardiovascular compromise, including decreased systolic function, hypotension, and arrhythmias, can be seen with hypocalcemia.\textsuperscript{125} In critically ill patients, cardiovascular findings are likely the most often seen because of continuous telemetry monitoring. Central nervous system manifestations of hypocalcemia are usually vague and include symptoms such as anxiety, irritability, depression, psychosis, and confusion.\textsuperscript{105,125}

**Morbidity and Mortality**

Many reports detail increased mortality among critically ill patients with hypocalcemia.\textsuperscript{132,133,137-139} A multicenter retrospective epidemiological study of 7,024 critically ill patients with 177,578 ionized calcium measurements (corrected to a pH of 7.4) showed a progressive increase in hospital and ICU mortality with worsening degrees of hypocalcemia. Multivariate logistic regression revealed that an ionized calcium concentration of 0.8 mmol/L or less using the lowest recorded value during the ICU stay was significantly associated with ICU and hospital mortality (similar findings were observed for a maximum ionized calcium concentration greater than 1.4 mmol/L).\textsuperscript{134} The potential influence of hypocalcemia on mortality deserves further investigation in prospective studies.

**Management**

Management of hypocalcemia in the critically ill population has not been well studied. In fact, no trials have evaluated the impact of parenteral calcium supplementation on outcomes or complications in critically ill patients.\textsuperscript{140} This is of particular concern, given that animal models with sepsis and trauma show increased mortality and end-organ dysfunction with calcium administration and potential protective effects of
hypocalcemia and/or calcium antagonism. Regardless, clinicians must make decisions every day regarding calcium supplementation. Although an agreement that intravenous calcium should be provided to patients who are hypocalcemic with symptoms can be assumed, particularly in cardiovascular compromise, many other questions remain. These include the proper threshold for supplementation among asymptomatic patients, method of calcium replacement (i.e., intermittent vs. continuous intravenous infusion), choice of calcium salt (gluconate vs. chloride), and amount of calcium to administer.

With respect to treatment threshold in asymptomatic patients, some experts recommend reserving treatment unless the ionized calcium is 0.8 mmol/L or less, whereas others suggest a more conservative threshold of 1 mmol/L or less in an attempt to prevent the development of cardiac sequelae. Trials have not been conducted to compare these two recommended thresholds. However, one small trial evaluating hemodynamic changes associated with calcium supplementation in hemodynamically compromised patients with hypocalcemia may assist clinicians in identifying a treatment threshold. In a prospective observational trial, Vincent and colleagues administered calcium chloride 1 g intravenously over 10 minutes to 17 consecutive ICU patients with hypocalcemia (ionized serum calcium less than 1.05 mmol/L) who were undergoing invasive cardiac monitoring. The mean baseline ionized calcium was 0.91 ± 0.12 mmol/L, which rose to 1.11 and 1.09 mmol/L at 30 and 60 minutes post-infusion. In addition, at 30 and 60 minutes post-infusion, a statistically significant rise in mean arterial pressure (from 77.2 mm Hg to 89.9 and 88 mm Hg, respectively) and left ventricular stroke work index was observed, showing improved vascular tone and myocardial contractility compared with baseline. A non-significant rise in cardiac index was observed as well, whereas no other changes were made in hemodynamic management (i.e., vasopressor escalation) during the time of intravenous calcium administration and evaluation. In light of these findings, and those of select case reports, an ionized calcium target of greater than 1 mmol/L may be considered in patients who are hypocalcemic with systolic dysfunction and/or hypotension. Currently,
no data are available to suggest that targeting a normal ionized calcium concentration (1.12–1.33 mmol/L) is more beneficial than a concentration greater than 1 mmol/L.\textsuperscript{131}

Two intravenous calcium products are currently available in the United States, calcium gluconate and calcium chloride, both 10% solutions (i.e., 1 g per 10 mL). Calcium gluconate contains 4.65 mEq of elemental calcium per gram, whereas calcium chloride contains 13.6 mEq of elemental calcium per gram. Therefore, calcium chloride is about 3 times more potent than calcium gluconate, and there are no direct trials comparing these two agents for calcium supplementation. Because calcium is a vesicant, both agents should be administered by a central venous access device. Dosing recommendations for intravenous calcium supplementation have been provided in several publications,\textsuperscript{105,143-145} but such recommendations appear to be based primarily on opinion rather than available data. In many cases, calcium administration by continuous or prolonged intravenous infusion is recommended. However, continuous administration may not be practical in most critically ill patients because of incompatibility with other infusions (e.g., medications, phosphate replacement, parenteral nutrition) and subsequent need for a dedicated or additional central venous access device. In the absence of data confirming the superiority of continuous to intermittent intravenous infusion, no ideal strategy is recommended for critically ill patients. Intermittent intravenous calcium administration appears to be the most practical; limited available data to support this strategy are provided in Table 3.10.\textsuperscript{146,147}

In accordance with targeting an ionized calcium concentration of 1 mmol/L or greater (in contrast to normalization), supplementation with 2 g of calcium gluconate intravenously over 2 hours through a central venous access device for critically ill patients with an ionized calcium of less than 1 mmol/L, regardless of the presence or absence of symptoms, appears safe. In patients who are hypertensive, it is recommended to withhold calcium supplementation unless the ionized calcium is less than 0.8 mmol/L or the patient is symptomatic. Repeat laboratory assessment should be conducted 2–12 hours post-infusion,
with further supplementation if indicated. In addition, management should include interventions for correctable underlying etiologies, such as hyperphosphatemia. Further research is needed to delineate the impact of intravenous calcium administration on outcomes in critically ill patients.

**HYPERCALCEMIA**

Hypercalcemia is defined as an ionized calcium concentration greater than 1.33 mmol/L (or a total serum calcium greater than 10.5 mg/dL). In general, hypercalcemia is not a disorder commonly associated with critical illness, and thus, the incidence among critically ill patients is relatively low (3.4–15%), although one large study showed an incidence of 23%. Clinical manifestations vary widely, are associated with reduced activity or slowing of the affected organ systems (in contrast to an excitatory state associated with hypocalcemia), and progress in severity as the calcium concentration rises. Hypercalcemia can affect the CNS (resulting in apathy, somnolence, and/or coma), cardiovascular system (hypertension, bradycardia, and cardiac arrest), GI system (nausea/vomiting, constipation, and ileus), muscular system (fatigue, bone pain, and/or fractures), and genitourinary system (polyuria, nephrolithiasis, and oliguria). As mentioned earlier, an ionized calcium greater than 1.4 mmol/L was independently associated with increased ICU and hospital mortality in a large, multicenter retrospective study; however, this has yet to be confirmed prospectively.

Hypercalcemia may be a result of excessive vitamin D or calcium intake, may be medication-induced (e.g., thiazide diuretics), or may be the result of granulomatous diseases (e.g., tuberculosis), excessive immobility, Paget disease, or familial hypocalciuric hypercalcemia. Most often, hypercalcemia is a result of malignancy and/or primary hyperparathyroidism. As such, readers are encouraged to visit the chapters related to oncologic and endocrine emergencies for details regarding the management of hypercalcemia.
ELECTROLYTE PROTOCOLS

Protocol-driven, in contrast to prescriber-driven, electrolyte replacement appears to have become rather common in daily practice. Although variations exist, protocol-driven electrolyte replacement entails the use of a standing order-set executed by a prescriber that provides the bedside nurse the authority to administer electrolyte replacement doses as needed on the basis of observed laboratory results (and may also provide standing orders for follow-up monitoring post-replacement). The utility of protocol-driven electrolyte replacement has been evaluated in several single-center before-and-after investigations.\textsuperscript{149-152} Overall, protocol-driven electrolyte replacement has been shown to reduce the time to electrolyte administration\textsuperscript{149,150} as well as the number of missed electrolyte replacement doses.\textsuperscript{149-151} Certain studies also report increased efficacy by way of a higher percentage of “normalized” serum concentrations post-replacement with protocol versus prescriber-driven dosing, particularly with respect to potassium.\textsuperscript{151,152} In addition, physicians and nurses report high satisfaction with protocol-driven electrolyte replacement.\textsuperscript{150} Figure 3.6 provides an example of protocol-driven electrolyte replacement for a critically ill patient with a central venous access device.

CONCLUSION

Electrolyte disorders are prevalent among critically ill patients and confer the risk of adverse sequelae. Patients with severe symptoms require prompt evaluation and intervention. Unfortunately, limited primary literature exists to guide decisions regarding the management of electrolyte disorders in the critically ill population, and as such, clinicians are often left with only their clinical judgment and little formal training. In particular, well-designed, prospective trials are needed to determine the ideal management strategy for severely symptomatic hyponatremia. Finally, and perhaps of greatest importance, critical care clinicians should focus their efforts on identifying risk factors and appropriately intervening before development of electrolyte disorders.
or associated clinical manifestations. Use of protocol-directed electrolyte replacement appears to be a step in the right direction.

LEARNING OBJECTIVES

1. Evaluate the applicability of a given predictive equation for determining caloric requirements in a critical care population based on factors such as age and weight.

2. Discuss the appropriateness of permissive underfeeding in a given patient scenario based on the route of feeding and patient characteristics, including malnutrition.

3. Evaluate the role of individual nutrients, such as glutamine, arginine, antioxidants, and omega-3 fatty acids, in the nutritional regimen for critically ill patients.

4. Discuss the impact of various dialysis procedures (hemodialysis, continuous venovenous hemofiltration, continuous venovenous hemodialysis, hemodiafiltration) on nutritional goals of the critically ill patient.

5. Evaluate a protocol for pancreatic enzyme administration with enteral nutrition.

ABBREVIATIONS IN THIS CHAPTER
INTRODUCTION

Depriving the human body of adequate calories and nutrients results in death within 6–12 weeks in young, healthy men only consuming water to avoid dehydration.\(^1\) Altered metabolism in critically ill patients is associated with more rapid nutritional deterioration than expected from reports in healthy individuals or those having famine, and poor
outcomes are correlated with malnutrition in the critically ill patient.\textsuperscript{2} Providing full nutrient requirements to the critically ill patient as soon as possible would, therefore, seem rational. Unfortunately, despite ongoing research and many randomized controlled trials during the past 2 decades, there are no decisive answers regarding the best time to feed, where or how to feed, and what to feed the critically ill patient. What seems like an answer from early studies is often of no benefit—or worse, is harmful to some patients—after further data analysis or more rigorous studies. This chapter explores available information and the many controversies related to nutrition support for critically ill patients in intensive care unit (ICU) settings.

**MALNUTRITION IN THE ICU**

Malnutrition has a prevalence of 20\%–60\% in hospitalized patients, depending on the criteria used.\textsuperscript{3-5} Most studies do not use rigorous criteria to define malnutrition, do not clearly delineate criteria for critical illness, and often depend on parameters negatively influenced by non-nutritional factors. Simply defined, malnutrition is abnormal nutrition related to macronutrients or micronutrients. As commonly used, malnutrition refers to undernutrition, although obesity also presents nutritional challenges, especially when metabolic alterations associated with critical illness are present. Critically ill patients are at particular risk of malnutrition because of increased nutritional demands and altered metabolism that result in far different clinical consequences than simple starvation.

The hallmark of the stress response in critical illness as related to nutrition is failure to adapt energy and protein use to restore homeostasis, which would otherwise occur in simple starvation. Neuroendocrine and inflammatory components of the stress response culminate in hyperglycemia, insulin resistance, accelerated protein catabolism, diminished efficiency of protein use, loss of skeletal muscle, and reduced lean muscle tissue.\textsuperscript{6-10} Activation of the sympathetic nervous system occurs within minutes of a stress event, followed within hours by activation of the hypothalamus-pituitary axis.
and release of thyroid-stimulating hormone, growth hormone, adrenocorticotropic hormone, and others. Growth hormone, catecholamines, and cortisol serve as cell mediators acting in conjunction with various hormones to drive the inflammatory response and increase the conversion of protein to glucose through the process of gluconeogenesis. Excessive glucose production by the liver is a major contributor to stress hyperglycemia. Peripheral resistance to the effects of insulin, thyroid hormone, growth hormone, and cortisol affects the metabolism of glucose, protein, and fat through the post-injury phase. Cytokines released as part of the inflammatory component cause weight loss, protein breakdown, and lipolysis, in addition to triggering anorexia.

**Assessment of Nutritional Status**

Longer length of stay (LOS), increased complications, and higher mortality have been associated with hospitalized patients identified as being at nutrition risk or malnourished. Nutrition screening is intended to identify patients who would benefit from a more comprehensive nutrition evaluation, yet some nutrition factors are used in both screening and assessment. Nutrition assessment, as defined by the American Society for Parenteral and Enteral Nutrition (ASPEN), is “a comprehensive approach to diagnosing nutrition problems that uses a combination of the following: medical, nutrition, and medication histories; physical examination; anthropometric measurements; and laboratory data.” In addition, from a practice or research perspective, nutrition assessment results should correlate with outcomes. In a systematic review of studies including construct or criterion validity versus a reference method, or predictive validity related to outcomes such as mortality, LOS, or complications, 32 nutrition screening or assessment tools used in hospitalized patients were identified. The tools included individual parameters and scoring systems using a combination of factors. A few tools performed fair to good for determining nutrition status or predicting outcomes in specific non-ICU patient populations; however, none performed well across all
populations, and none was designed specifically to assess critically ill patients.

Most anthropometric, biochemical (laboratory), and clinical parameters used for nutrition screening and assessment have significant limitations in the critical care setting because of fluid changes, effects of inflammation, sedation, and loss of consciousness, limiting ability to obtain data requiring patient participation (weight and dietary histories, previous gastrointestinal [GI] symptoms, functional parameters), and effects of medications commonly used in ICUs. Recorded weight has been found in less than 20% of charts during quality audits of hospitalized patients. Acute-phase proteins, including serum albumin, transthyretin (prealbumin), and transferrin, are not valid in critically ill patients as markers of nutritional status and do not predict outcome in this population.

Physical assessment and anthropometric measures commonly used to evaluate critically ill patients enrolled in clinical research should be applicable in the non-research setting and show clinical utility to allow better alignment of practice with research results. An analytic observational study evaluated the performance of individual bedside measures used in clinical research to determine clinical usefulness for identifying malnourished critically ill patients and ability to predict outcomes, primarily increased risk of mortality. Measures evaluated did not require patient participation and were collected by trained assessors for 1,363 patients in 31 hospitals from 31 ICUs in Australia and New Zealand. Five measures, including mid-upper-arm circumference, mid-arm muscle circumference, subcutaneous muscle wasting and fat loss (both assessed by physical assessment using subjective global assessment [SGA] criteria), and body mass index (BMI) analyzed as a continuous variable, showed statistically significant clinical usefulness and predictive ability. However, the strength of clinical utility was poor for any individual measurement. The area under the receiver operating characteristic curves (aROCs) ranged from 0.52 to 0.56, and the 95% confidence interval (CI) did not exceed 0.60. An aROC under 0.70 is considered a poor test; acceptable performance in sensitivity and specificity is typically based on a minimum performance
threshold of 0.70 (aROC 0.70). Multivariate analysis identified the best combination of factors showing independent clinical usefulness and predictive ability to be mid-arm-muscle-circumference and subcutaneous fat loss assessed by SGA criteria. Triceps skinfold thickness and BMI categorized by World Health Organization (WHO) breakpoints failed to show a significant predictive ability for mortality at hospital discharge.

The statement on malnutrition by the Academy of Nutrition and Dietetics and ASPEN, called the Consensus Statement on Malnutrition, uses an etiology-based construct incorporating inflammation as a primary factor distinguishing starvation-related malnutrition (inflammation not present) from disease- or injury-related malnutrition with inflammation present. Chronic disease–related malnutrition is characterized by mild to moderate inflammation, as occurs in organ failure and sarcopenic obesity; acute disease– or injury-related malnutrition is associated with marked inflammation, as noted with major infections, trauma, and burns. Critically ill patients may develop acute on top of chronic disease–related or starvation-related malnutrition; however, pure starvation-related malnutrition is rare in this population. Recognizing the importance of inflammation in disease- or injury-related malnutrition is a starting point for assessing nutrition status in critically ill patients; however, other measures or combinations of factors are also necessary. The Consensus Statement on Malnutrition requires two of six characteristics—weight loss, reduced nutrition intake, edema, muscle wasting, fat loss, and impaired functional status—to be present for the diagnosis of malnutrition.

Assessment of muscle wasting and fat loss is required when using either the Consensus Statement on Malnutrition or SGA. Conducting a nutrition-focused physical examination to assess muscle and fat can be difficult in critically ill patients because of the effects of edema, fluid overload, presence of lines and tubes, distortion of facial tissue from oxygen masks or mechanical ventilation tubes, and body tissue alterations related to lying in bed and fluid redistribution. The quadriceps region is an area where skeletal muscle wasting can be identified in critically ill patients. The deltoids and temporalis
muscles are other important areas to assess for muscle wasting, although guidelines for evaluating and rating of seven muscle regions (temple, clavicle bone, shoulder and acromion bone, scapula and upper back, anterior thigh, patella, and posterior calf) and 12 muscle groups typically included in a complete nutrition-focused physical examination are available.\textsuperscript{18,22} Loss of subcutaneous fat can be assessed by physical examination in three regions using guidelines for nutrition-focused physical examination; however, the upper arm region overlying the triceps may be the most readily assessed and least likely to be altered by non-nutritional factors in critically ill patients. Promising areas of research for assessing muscle and fat changes in critically ill patients include use of computed tomography (CT) and ultrasound techniques.\textsuperscript{23,24} A small study of 56 mechanically ventilated patients suggests that CT also detects sarcopenia more readily than SGA.\textsuperscript{25} Patients classified as normal nourished by SGA were misclassified 50% or more of the time according to detection of sarcopenia using CT. Patients more likely to be misclassified in this study were male, minority, and overweight or obese. Despite its apparent limitations in identifying sarcopenia and need for patient participation, SGA has been shown to be an independent predictor of length of hospital stay in several patient populations and for LOS, readmission to the ICU, and probability of death in critically ill patients.\textsuperscript{5,11,26-28}

The Nutrition Risk in the Critically Ill (NUTRIC) score was developed specifically to identify the critically ill patients most likely to benefit from nutritional therapy and is calculated from age, Acute Physiology and Chronic Health Evaluation II (APACHE II), Sequential Organ Failure Assessment (SOFA), number of comorbidities, and days from hospital to ICU admission.\textsuperscript{29} Interleukin-6 is included in the NUTRIC calculation when available. A modified NUTRIC score without interleukin-6 has been validated in 1,199 critically ill patients with multi-organ failure.\textsuperscript{30} Nutritional adequacy has a high positive association with 28-day and 6-month survival in patients with high modified NUTRIC scores. The modified NUTRIC score, however, identifies different patients than does SGA.\textsuperscript{31} Calculation of the modified NUTRIC score and SGA in the same patients identified 26% (36 of 139) and 80% (111 of 139),
respectively, as candidates for nutrition support or as malnourished. Using these two methods plus the institution’s routine screening method, only 6.7% of patients were determined to be at nutrition risk and malnourished by all three methods. In this small study of 294 patients admitted to the ICU with 139 deemed at nutrition risk or malnourished by at least one of the three methods, the modified NUTRIC score identified patients with the longest hospital and ICU LOSs, whereas SGA identified patients more likely to be discharged to a rehabilitation facility.

Determining nutrition status in critically ill patients is difficult; limitations exist for all available assessment methods. However, assessing nutrition status is necessary to appropriately apply available research results and clinical guidelines. Using a combination of methods may therefore be rational. The modified NUTRIC score should be considered as one of the combination of methods because it was specifically developed and validated for critically ill patients.²⁹,³⁰ However, compared with other assessment methods, modified NUTRIC identifies a relatively small percentage of patients as most likely to benefit from nutritional therapy; other patients who would conceivably benefit are not identified.³¹ The Consensus Statement on Malnutrition is a second method to consider as part of a combination of assessment methods because it is one of the few methods to incorporate inflammation as a factor in defining the type and severity of malnutrition.²¹ Use of SGA in combination with the other two methods could also be considered. It is unclear whether combining assessment using the Consensus Statement on Malnutrition criteria and SGA would provide any added benefit for clinical utility or predictive ability regarding outcomes in critically ill patients compared with one of the methods alone. Several components of SGA are incorporated into the Consensus Statement on Malnutrition; however, SGA includes specific areas for assessment of fat and muscle, as well as assessment of GI symptoms and metabolic stress.¹⁸ Patients likely to require discharge to a rehabilitation facility are identified by SGA; the Consensus Statement on Malnutrition has not been evaluated in this context, although inclusion of functional status makes it reasonable to expect
the Consensus Statement on Malnutrition to perform similarly to SGA in this respect.\textsuperscript{21,31} No studies comparing the Consensus Statement on Malnutrition criteria and SGA are available, including none in critically ill patients and none evaluating the ability to predict patient outcomes. Nor has routine use of both the NUTRIC or modified NUTRIC score and the Consensus Statement on Malnutrition criteria in critically ill patients been evaluated, despite an apparent rationale for the combination.

**Timing and Route of Nutrition Support**

When to feed critically ill patients remains controversial. The route of feeding (enteral vs. parenteral), volume of feeding (trophic or partial feeding vs. full goal), and patient characteristics, including disease severity, comorbidities, and degree of malnutrition, all influence when to feed. The debate over when feeding should start is significantly influenced by the route of feeding. Four major clinical guidelines addressing the care of critically ill patients, including joint guidelines of the Society of Critical Care Medicine (SCCM) and ASPEN, Canadian Clinical Practice Guidelines, European Society for Parenteral and Enteral Nutrition (ESPEN) guidelines on enteral nutrition (EN), and the Surviving Sepsis Campaign, recommend initiating EN within 24 or 48 hours of ICU admission when patients cannot tolerate oral intake and are expected to remain in the ICU.\textsuperscript{32-35} The recommendation for early EN is repeated in the ESPEN guidelines on parenteral nutrition (PN).\textsuperscript{36} No new studies with significantly different results were available for the 2015 update to the Canadian Clinical Practice Guidelines, and the recommendation was continued without change.\textsuperscript{37} The strength of the recommendation is not strong; the Canadian Clinical Practice Guidelines reported only a trend toward a reduction in mortality and infectious complications with early EN.

There are no randomized studies showing a survival benefit with early EN in critically ill patients, with or without sepsis. Statistically significant reductions in mortality (odds ratio [OR] 0.34; 95% confidence interval [CI], 0.14–0.85) and pneumonia (OR 0.31; 95% CI, 0.12–0.78) were noted with EN initiated within 24 hours of ICU
admission in a meta-analysis of six randomized controlled trials.\textsuperscript{38} A total of 234 patients were analyzed for the meta-analysis; 117 were trauma patients, and only 28 patients were mechanically ventilated. Despite inclusion criteria intended to select only trials with sound methodology, several risks of bias were present.\textsuperscript{39} Benefits in secondary outcomes attributed to early EN include preservation of GI integrity, decreased LOS in the hospital and ICU, lower risk of infection, and reduced time on mechanical ventilation.\textsuperscript{40-43} When randomized trials reporting clinical outcomes with early EN versus delayed EN or no nutrition were evaluated for the presence of methodological bias, all 15 trials meeting rigorous inclusion criteria showed substantial heterogeneity, and none were low risk of bias.\textsuperscript{39} An early review of 111 studies also found substantial methodologic limitations in trials evaluating nutrition support in critically ill patients.\textsuperscript{44} Two trials encompassing 87 total patients were classified as “more robust” and assessed alone versus 10 “less robust” trials with 632 total patients evaluated for mortality and 11 trials with 580 total patients for infectious morbidity; neither mortality nor infectious morbidity was significantly different.\textsuperscript{39} Only one of the trials identified as more robust was of critically ill patients.\textsuperscript{45} Overall, less robust trials were the only ones to show a clinically significant mortality benefit for early EN. The same is true for infectious morbidity; however, there was little difference in the size of the estimated effect of bias between more robust and less robust studies in this group. Pneumonia, days on mechanical ventilation, and ICU LOS were not different between more and less robust trials in this evaluation, and no data were reported for non-infectious morbidity, adverse events, hospital LOS, and cost in more robust trials. The authors concluded that randomized controlled trials with low bias are needed before early EN can be considered beneficial compared with late EN or no nutrition. Conversely, there is no evidence that early EN is harmful when initiated in appropriate patients, defined as after adequate fluid resuscitation has been completed and the patient is hemodynamically stable with no contraindication to EN.\textsuperscript{32,33}

Guidance for early EN in patients who require vasoactive agents is
limited because of a lack of adequate studies. The Canadian Clinical Practice Guidelines and the ESPEN guidelines indicate uncertainty regarding this patient population.\textsuperscript{33,34} The SCCM/ASPEN guidelines clearly state that small bowel EN should be held in patients with a mean arterial blood pressure under 60 mm Hg and when high doses or escalating doses of vasoactive agents are required to maintain perfusion.\textsuperscript{32} Cautious use of EN with close clinical monitoring for any signs of intolerance is supported at that lowest level of evidence for patients receiving “stable low doses of vasopressor agents,” but low dose is not defined.

Reports of nonocclusive mesenteric ischemia and bowel necrosis in hemodynamically unstable patients receiving EN fuel the caution and uncertainty of early EN in this population.\textsuperscript{46-48} Administration of EN is postulated to cause inadequate intestinal perfusion resulting in necrosis as further compromise of splanchnic blood flow on top of that caused by hypotension and the underlying disease process occurs. Although cases of ischemia and necrosis have occurred in hemodynamically unstable patients receiving EN, no studies have adequately evaluated the premise related to perfusion and EN administration. In addition, individual vasoactive agents, and sometimes different doses of the same agent, exert different GI effects and may produce different responses with early EN.\textsuperscript{47}

Changes in hemodynamic parameters, including decreased mean arterial pressure and systemic vascular resistance in addition to increased cardiac index and stoke volume, have been shown with early EN in patients receiving vasopressor agents after cardiac surgery.\textsuperscript{49} Patients in this prospective study required cardiopulmonary bypass during surgery the previous day and were receiving stable doses of dobutamine or dobutamine plus norepinephrine; EN was administered by a postpyloric tube. The study collected baseline data during 2 hours of fasting, followed by data collection during 3 hours of EN. Study limitations, including an extremely small sample size of only nine patients, none with evidence of bowel ischemia, and the short duration of EN make it problematic to extrapolate the data to patient care. Another small prospective study of patients who were post-cardiac
surgery compared 23 patients receiving dopamine, dobutamine, norepinephrine, or a combination of these medications at doses well below maximum clinical doses with 16 patients not requiring vasoactive therapy.\textsuperscript{50} Splanchnic blood flow increased with EN, as indicated by increased indocyanine green clearance after EN compared with before EN. Patients receiving vasopressor support tolerated EN but averaged about half of the 25-calorie/kg/day goal. A larger retrospective study using information in a multi-institution ICU database evaluated 1,174 patients requiring mechanical ventilation for over 2 days and requiring vasopressor agents (norepinephrine, epinephrine, dopamine, or phenylephrine).\textsuperscript{51} The early enteral group was composed of 707 patients receiving EN within 48 hours of starting mechanical ventilation; the remaining 467 patients constituted the late enteral group. Results showed a benefit of early EN on both ICU and hospital mortality, with the patients receiving several vasopressor agents during the first 2 days of ventilatory support benefiting the most (OR 0.36; 95% CI, 0.15–0.85). Patients requiring vasopressor support for more than 2 days also had greater benefit with early EN (OR 0.59; 95% CI, 0.39–0.90). After correcting for confounders, early EN was associated with a 30%–35% decreased risk of death according to Cox proportional hazards analyses. Ventilator-associated pneumonia, ICU LOS, and ventilator-free days were not statistically different, and no evidence of harm was found with early EN. Assessment at 28 days indicated no significant change in results. Slight differences did exist between groups, with patients in the early EN group being slightly older but also having a lower severity of illness with two of the three methods assessed. A respiratory diagnosis was also more likely at ICU admission in the early EN group. These results support the cautious use of early EN in patients requiring vasopressor agents. A large randomized trial is now needed to confirm the retrospective data.

Until more definitive answers are available, several factors should be considered when deciding whether a patient requiring vasopressor support is appropriate for a trial of early EN. Patients already at risk of nonocclusive mesenteric ischemia are likely to be at higher risk when starting EN. This includes patients with a history of sepsis, major
infection, diabetes mellitus, smoking, or critical stenosis in the mesenteric vasculature, and older adult patients with cardiovascular disease or arrhythmia.\textsuperscript{48,52} Conditions present at the time of evaluation that suggest not proceeding with EN include low mean arterial blood pressure (consistently less than 60 mm Hg), increasing doses of vasoactive agents, cardiac failure resulting in a low flow state, active bleeding requiring ongoing transfusions, and requirement for massive fluid resuscitation. The vasoactive agent being administered and its dose also need to be considered. One recommended classification of a high-dose vasopressor agent indicating greater caution for initiation of EN is as follows: dopamine over 10 mcg/kg/minute, epinephrine or norepinephrine over 5 mcg/minute, vasopressin above 0.04 unit/minute, and milrinone above 0.375 mcg/kg/minute.\textsuperscript{48} Phenylephrine has been associated with nonocclusive mesenteric ischemia and may be more risky than other pharmacologic agents when EN is provided.\textsuperscript{52} In addition, partial enteral support may be more appropriate than full support, at least when EN is first initiated. Close clinical monitoring for any signs of intolerance is essential.\textsuperscript{32,48}

Optimal timing for initiation of PN has not been determined; research has produced mixed results. From a practice standpoint, knowing the most appropriate time to initiate PN often becomes a question of nutrition versus no nutrition in the first few days of ICU admission because early EN is often not achievable in patients either with or without prior malnutrition. In a retrospective observational study evaluating actual practices for early EN in critically ill patients, 60.8% of patients met a goal of EN within 48 hours of ICU admission; 13.3% received EN within 24 hours.\textsuperscript{53} The study was international in scope and included 2,946 patients from 158 ICUs, indicating that the problem of delay in initiating EN is widespread in ICUs.

Initiating PN within 24–48 hours of ICU admission if the GI tract cannot be used within 3 days is recommended by the ESPEN guidelines, whereas the SCCM/ASPEN guidelines recommend not initiating PN until after 7 days.\textsuperscript{32,36} The initial 2003 Canadian Clinical Practice Guidelines recommended against the routine use of PN in patients with an intact GI tract, and subsequent updates, including the
2015 update, have continued this recommendation. However, the 2015 update included an additional statement to consider PN when a relative contraindication to early EN existed in patients with high nutritional risk. The American Thoracic Society, together with four other professional societies, included not using PN within the first 7 days of ICU admission in adequately nourished patients as the third of five recommendations for its Choosing Wisely Top 5 list in critical care medicine. All recommendations or guidelines assume no preexisting malnutrition.

The SCCM/ASPEN guidelines rely heavily on two meta-analyses comparing no nutrition support with use of PN for their recommendations. The first meta-analysis reported significantly lower infectious morbidity with no nutrition support (relative risk [RR] 0.77; 95% CI, 0.65–0.91) in critically ill patients without preexisting malnutrition than in patients receiving PN. The difference in complications was not statistically significant, although a trend toward lower overall complications was reported. A significant increase in mortality with PN (RR 1.78; 95% CI, 1.11–2.85) was noted in the second meta-analysis. A trend toward more complications was found with PN compared with no nutrition support. The impact of adequate glucose management on outcome was not yet recognized when the studies in these two meta-analyses were completed; therefore, it is unclear whether inadequate glucose control contributed to worse outcomes with PN. The eventual risk of harm from not feeding was recognized when determining the point at which PN would be better than no nutrition in the guidelines. Data indicated that after 14 days with no nutrition compared with providing PN, mortality and hospital LOS increased in hospitalized patients. The SCCM/ASPEN guidelines selected over 7 days as their recommendation for initiating PN. Guidelines from ESPEN were swayed by a meta-analysis of 11 trials, which included both elective surgery and critically ill patients when early EN was not feasible. Better survival was shown when PN was initiated within 24 hours of ICU admission than when EN was initiated late (OR 0.29; 95% CI, 0.12–0.70). No subanalysis was conducted to separate effects on critically ill patients compared with elective surgery.
patients, despite the heterogeneity between these two populations.

Studies available after both the ESPEN and the SCCM/ASPEN guidelines were published in 2009 have shown variable outcomes related to initiating PN in ICU patients, as shown in Table 4.1. Trials as a whole define early nutrition support, either EN or PN, as starting within 48 hours of ICU admission and late as starting after 48 hours. The term delayed PN is sometimes used to define the initiation of PN specifically after ICU day 7. These definitions are used here unless otherwise specified.

An observational study of 703 critically ill patients with a medical diagnosis and remaining in the ICU over 72 hours found that early PN better met goals for calories (74.1% ± 21.2%) and protein (71.5% ± 24.9%) than either late PN (57.4% ± 22.7% calories, 53.2% ± 22.7% protein) or late EN (42.9% ± 21.2% calories, 38.7% ± 21.6% protein). Although the 83 patients initiated on early PN received more of their goal calories and protein than the 79 patients receiving late PN or the 541 patients receiving late EN, there was no statistically significant difference in mortality or hospital and ICU LOS.

The trial known as Early Parenteral Nutrition Completing Enteral Nutrition in Adult Critically Ill Patients, or EPaNIC, compared early PN, as recommended by ESPEN, with PN initiated after 7 days in the ICU (delayed PN), as recommended in the SCCM/ASPEN guidelines. The early PN group had 2,312 patients, and the delayed PN group had 2,328 patients; all patients were at nutritional risk. Hospital, ICU, and 90-day mortality did not differ between early and delayed PN. Overall, delayed initiation of PN was associated with better outcomes than was early PN, including a greater likelihood of live discharge from the ICU at day 8, earlier ICU discharge by a median of 1 day (HR 1.06; 95% CI, 1.00–1.13), earlier hospital discharge by a median of 2 days (HR 1.06; 95% CI, 1.00–1.13), fewer new infections, a lower percentage of patients requiring mechanical ventilation for more than 2 days, and a shorter duration of renal replacement therapy. Inflammation measured by C-reactive protein was higher, and more patients had hypoglycemia with delayed PN. Functional status was not different at discharge.

The EPaNIC study design was different from that of previous
studies evaluating the timing for PN initiation because patients were randomized to early versus late PN as a supplement to inadequate EN initiated early; the goal for PN was to meet calorie requirements with PN plus EN.\textsuperscript{60} Patient demographics were different from those in many studies evaluating nutrition support in ICU patients; enrolled patients were about 90% surgery patients, and more than 50% appeared to be elective admissions. Cardiac surgery patients represented about 60% of each group. However, outcomes in cardiac surgery patients were no different from those in the entire study population. Severity of illness appeared to be relatively low, given that most patients had a short ICU LOS and under 10% ICU mortality. A predefined post hoc subgroup analysis was performed in the 517 patients at high nutritional risk, based on complex surgery with a contraindication to early EN and no nutrition by ICU day 7. In the high-risk group, patients receiving delayed PN had a lower infection rate (29.9% vs. 40.2%) and were more likely to be discharged alive from the ICU sooner (HR 1.20; 95% CI, 1.00–1.44) than were patients in the early PN group. Early PN, with or without concomitant EN, was detrimental compared with delayed PN in the patient population studied, including patients at nutritional risk.

| Table 4.1 | Studies on Initiating PN in Critically Ill Patients Published Since ESPEN and SCCM/ASPEN Guidelines in 2009 |
Because of criticism of the original EPaNIC trial, a post hoc analysis was conducted to determine whether severity of illness influences the results. The total EPaNIC population was divided into quartiles according to severity of illness as defined by the Acute Physiology and Chronic Health Evaluation II (APACHE II) score. The APACHE II quartiles in order of increasing severity of illness were 10–13, 16–18, 22–30, and 35–41. No quartile showed a benefit from early PN with respect to live discharge from the ICU at day 8. Delayed PN remained a benefit across all quartiles when evaluating the percentage of patients developing a new infection; quartiles for APACHE II of 16–18 and 22–39 showed a decrease in the percentage of patients developing new infection. Adverse effects of early PN initiation were not related to the severity of illness in this post hoc analysis.
A small preplanned substudy of EPaNIC evaluated changes in muscle and adipose tissue in 15 patients admitted to the ICU with intracranial bleed, isolated brain trauma, or subarachnoid hemorrhage. Inclusion criteria required a clinical indication for CT scanning within 48 hours of ICU admission and repeat CT scanning scheduled at ICU admission for 1 week later. Six demographically matched healthy volunteers served as controls and underwent repeat CT scanning at an interval of 7 days. Repeat quantitative CT images, both mid-femur and abdominal, were used to estimate muscle and adipose tissue volume. Ten patients were in the early PN group of EPaNIC and five in the delayed PN group. Muscle wasting occurred with both early and delayed PN. Early PN was associated with increased lipid and water content of muscles. According to this small study, early PN does not prevent muscle wasting better than delayed initiation of PN and may result in more accumulation of water and fat in the muscles.

The EPaNIC study primarily evaluated the addition of PN, either early or late, in patients receiving early EN to bring the total caloric intake to 100% of estimated requirements. An observational study of 2,920 patients from 226 ICUs compared both early and late addition of PN to EN with early EN alone. This study design allows a better comparison of PN effects with EN than does the EPaNIC design because there was a group randomly assigned to early EN alone. A diligent attempt to use the GI tract in study patients is suggested by only a small percentage of the total study population in the two PN groups: 188 patients (6.4%) with PN added early and 170 patients (5.8%) with PN added late. Both PN groups of patients were more likely to have early and persistent GI dysfunction than were patients receiving only early EN, and the late PN group of patients had more persistent GI dysfunction than did patients with PN added early. Outcomes were worse with the addition of PN than with EN alone. Either early or late PN was associated with higher mortality and longer time on mechanical ventilation, and both ICU and hospital LOS were longer. Patients receiving early PN had a later discharge alive (HR 0.75; 95% CI, 0.59–0.96), as did patients receiving late PN (HR 0.64;
95% CI, 0.51–0.81). Subgroup analysis was conducted on high nutritional risk categories, including patients with EN intolerance, either early (258 patients) or persistent (379 patients), and those with a GI admitting diagnosis (178 patients). No benefit to early or late addition of PN was found in patients with either early or late GI intolerance. Compared with patients in the subgroup receiving EN alone, time to discharge alive was longer for patients with an admitting GI diagnosis for either early PN (HR 0.35; 95% CI, 0.19–0.63) or late PN (HR 0.62; 95% CI, 0.41–0.94).

In contrast to these and EPaNIC’s results, a much smaller study reported better outcomes when PN was added to inadequate EN for critically ill patients. The trial, often called the Supplemental Parenteral Nutrition trial, included 305 ICU patients from two centers and enrolled patients on ICU day 3. By default, this relatively late enrollment indicated that patients were at higher risk nutritionally, as did attention to patients with GI intolerance. Patients receiving less than 60% of goal calories from EN were randomized to supplemental PN (153 patients) on ICU days 4–8 or continued EN alone (152 patients). Calorie requirements were determined on ICU day 3 by indirect calorimetry or, if not available, set at 25 or 30 calories per kilogram per day using ideal body weight for women and men, respectively. Between days 4 and 8, patients receiving supplemental PN achieved their calorie goal; the EN group received 77% ± 27% of goal. The primary outcome was nosocomial infection rate after the intervention and was measured from day 9 to day 28. The supplemental PN group had a reduced nosocomial infection rate (HR 0.65; 95% CI, 0.43–0.97) together with fewer total infections per patient. The major discrepancy was in “other” infections post-intervention (4% in supplemental PN; 18% in EN group); most infections typically identified as problematic in critically ill patients (pneumonia, bloodstream, urogenital, and abdominal infections) appeared in a similar percentage of patients in the two groups. There was no definition of “other” infections.

Evaluation of 1,372 critically ill patients with a relative contraindication to EN showed no difference in the primary outcome of 60-day mortality between the half randomized to PN starting within 24
hours of ICU admission and those receiving standard care, including EN, PN, or no nutrition as determined by the attending physician. Nutrition support was initiated in standard care patients at a mean of 2.8 days after study randomization, which occurred within the first 24 hours of ICU stay. Neither EN nor PN was administered to 40.8% of standard care patients; at some time during their ICU stay, 43.7% received EN. Mechanical ventilation was required for about 1 less day with early PN, and coagulation failure averaged about ½ day less. Infection rates did not differ between groups, nor did organ failure (renal, pulmonary, hepatic, cardiovascular, and multisystem failure).

A randomized comparison of early PN with early EN, called the CALORIES trial, was conducted in 2,388 patients admitted to one of 33 participating ICUs. Inclusion criteria required no contraindications to either PN or EN. Nutrition was administered by the assigned route for 5 days (120 hours) unless the patient transitioned to a complete oral diet, was discharged from the ICU, or died before this time. No difference between PN and EN was found in the primary outcome of 30-day mortality (RR for PN 0.97; 95% CI, 0.86–1.08) or secondary outcome of mean number of treated infectious complications (0.22 vs. 0.21). Rates of hypoglycemia and vomiting were significantly less with PN, and increased liver function tests occurred more commonly. Other secondary outcomes did not differ between EN and PN, including days alive and free of organ support at 30 days, abdominal distention, ICU and hospital LOS, and death in the ICU, hospital, or at 90 days.

The CALORIES trial showed that early PN was not associated with worse outcomes than early EN. Mortality was not increased, nor was morbidity, including infectious risk. However, the patient population studied must be considered before widely extrapolating these data to critically ill patients, especially those at nutritional risk. Given the BMI and percentage of weight loss in the previous 6 months, more than 90% of the patients in the CALORIES trial were well nourished before ICU admission. Severity-of-illness scores were moderately high; the APACHE II score was slightly under 20, and the SOFA score was slightly below 10 in both groups. Vasoactive agents were required in 80%–85% and mechanical ventilation in 83%–84% of patients in both
groups. Protein provision was very low at 0.6–0.7 g/kg/day in both groups, and the calorie goal of 25 calories per kilogram per day was not reached in either group.

Taken as a whole, trials published since the ESPEN and SCCM/ASPEN guidelines became available in 2009 have added to the controversy regarding the best practice for nutrition support in critically ill patients. Early EN continues to be recognized as the best practice; however, many patients do not meet the goal of early EN. A concerted effort to initiate early EN should be made; however, PN now appears to be a more viable option for some patients than continued inadequate nutrition. Studies must be evaluated carefully to determine the study population, including severity of illness and nutritional status, and applicability of results to an individual patient. Patients with the greatest severity of illness and high nutritional risk are most likely to benefit from, and not be harmed by, early PN. The 2015 Canadian Clinical Practice Guidelines recommend consideration of early PN in patients at high nutritional risk with a relative contraindication to EN.

NUTRITIONAL GOALS—MACRONUTRIENTS

Paralleling the question of timing for nutrition support is the question of how much to feed the critically ill patient. Various methods are used to determine calorie goals, including measurement of metabolic substrates and products, predictive equations ranging from simple to complex, and fixed caloric targets based on weight. The doubly labeled water method is the gold standard for establishing caloric requirements, although clinical use is limited by the 1-week or more delay in obtaining results. Indirect calorimetry is the standard to which other methods for determining the resting energy expenditure are compared in the clinical setting. Nonetheless, the Canadian Clinical Practice Guidelines committee found insufficient data to make a recommendation on the use of indirect calorimetry compared with predictive equations during its initial guidelines development or for any subsequent updates. Limitations to indirect calorimetry include availability, cost, and decreased accuracy in the presence of several
commonly encountered ICU conditions including high oxygen requirements; leaks in the airway circuit from endotracheal cuffs, chest tubes, or bronchial-pleural fistulas; and removal of carbon dioxide by renal replacement therapy or extracorporeal systems. Determining an activity factor to account for energy expenditure above the resting state can also be problematic in the critical care setting, especially when patients are not comatose or heavily sedated.

Predictive equations use anthropometric data and other variables developed from regression analysis to predict caloric requirements of a specified population. Only a few predictive equations among the hundreds published were designed for use in critically ill patients. Many predictive equations used in the ICU were not developed or validated in this setting and are not accurate across the full range of ages and body habitus encountered in the critically ill population. Compared with indirect calorimetry in 202 ventilated patients, overall accuracy of various predictive equations ranged from 18% to 67%. Among the predictive equations tested, the Penn State equations incorporating Mifflin equations to account for demographic data (weight, height, age, sex) were the most accurate, had the lowest percentage of estimates over 15% different from measured, and were not biased overall or in any subgroups (young nonobese or obese, older adult nonobese or obese). The Mifflin equations themselves are supported by considerable evidence and widely used; however, in the critically ill population, the equations lack precision, have a 25% accuracy rate, and are consistently biased toward underestimating energy requirements. Harris-Benedict equations are widely used in the original form and various permutations; however, they are not recommended for use in critical care. Because of inaccuracies in the older adult group with obesity using almost all predictive equations, modified Penn State equations were developed for this population. Table 4.2 summarizes guideline recommendations for calorie goals and predictive equations commonly in use or designed specifically to estimate the resting energy expenditure for critically ill patients.

The question of how much to feed the critically ill patient is not
answered by determining energy expenditure. The effect of underfeeding versus full feeding on outcomes remains an area of investigation and ongoing discussion. Major guidelines do not agree on the best strategy, especially regarding the dose for PN, as shown in Table 4.3. As with the timing of nutrition support, the answer may depend on many factors, including the route of nutrition support and patient characteristics.

The Canadian Clinical Practice Guidelines show the progression in recommendations for underfeeding versus full feeding as well as some of the uncertainties in definitions and need for clarifications. When the initial Canadian Clinical Practice Guidelines were developed, data were insufficient to make a recommendation on achieving the target dose of EN except in patients with severe head injuries, where one trial indicated less infections and more rapid recovery but no difference in mortality when closer to goal calories and protein were fed. At the same time, the guidelines indicated that hypocaloric PN should be considered in specific patients, but there was no consensus on the definition of hypocaloric because of the inconsistency among studies. By the 2009 Canadian Clinical Practice Guidelines, the recommendation for EN implied that the target dose of EN should be considered for all critically ill patients rather than any specific subgroup. Starting in 2013, patients with acute lung injury (ALI) were identified as a group in whom trophic feeds should not be considered. Guidelines have not changed regarding hypocaloric PN since the 2007 clarification regarding insufficient data in specific populations (malnourished, obese patients, PN more than 10 days).

Studies evaluating hypocaloric feeding versus full nutrition have produced varied results. Hypocaloric feeding is not a standardized term with a defined caloric intake but varies from study to study and encompasses other terms used to categorize the degree of underfeeding. Trickle feeding is often defined by a rate of 10 or 15 mL per hour and trophic feeding as 25% or less of estimated requirements. These feeding amounts are intended to maintain gut integrity. The term permissive underfeeding is sometimes used to
signify about one-half of estimated requirements with a range of one-third to two-thirds of requirements typically used. Table 4.4 summarizes studies evaluating hypocaloric feeding versus goal or full feeding published after the guidelines from SCCM/ASPEN, ESPEN, and the Canadian Clinical Practice Guidelines committee in 2009. Interpretation and comparison of these studies is difficult because of differences in patient populations and nutrient provision. Inadequate differences between underfeeding and full feeding may confound the results in some studies (e.g., 59% vs. 71% of goal calories). Severity of illness appeared to vary between studies when assessing several parameters, such as the percentage of patients with sepsis enrolled, time on the ventilator, and average ICU LOS. In several studies, the average age was in the low to mid-50s range, a relatively young critically ill population, whereas the average age was in the lower 60s for other studies. Nutritional status was not always clarified or considered for study enrollment; thus, it is unclear whether patients at lower nutritional risk may have skewed results in some studies.

Most studies included BMI when comparing patient characteristics, which provides some indication of adequate calorie stores. The BMI could also signal the likelihood of response to varied nutrient provision. In an observational cohort study including 167 ICUs and 2,772 patients, mortality was unaffected by increased calorie provision in patients with a BMI of 25 kg/m² to less than 35 kg/m², whereas mortality was lower with increased calories on either side of this BMI range. Two studies with lower average BMI (26–28 kg/m²) and higher average age (61–63 years) showed a benefit to increased calorie and protein provision. However, in a study comparing early EN alone with the addition of either early or late PN, the early EN plus early PN group had a low BMI (24.5 kg/m²) and average age of 62.3 years versus 27.2 kg/m² and 58.4 years for the group receiving early EN alone. The early EN plus early PN group received the most adequate calories (81.2% of goal) and protein (80.1%) but had worse outcomes than the early EN alone group, where calorie and protein provision were considerably less (63.4% and 59.3%, respectively). The percentage of patients in either group with a respiratory diagnosis or sepsis (33.2% and 9.3% EN;
28.2% and 3.7% EN plus early PN, respectively) at ICU admission was much lower than in the study by Elke et al., where all patients had either sepsis (45%) or pneumonia (55%).\textsuperscript{41,63}

Two striking features when evaluating studies comparing underfeeding with full feeding are the nutrition goals and the actual nutrition provided with full feeding. Caloric goals are determined by various methods in the studies; none of the studies uses indirect calorimetry exclusively; some studies use methods with poor performance in critically ill patients, such as Harris-Benedict equations. This raises the question of whether appropriate calorie goals were established. Most studies were conducted during the acute phase of illness when exogenous calorie requirements are lower because of endogenous glucose production, which again raises the question of appropriate calorie goals. With calorie goals set at 30 calories per kilogram per day, or 25–30 nonprotein calories per kilogram per day, it is probable that full feeding was actually overfeeding and may have contributed to worse outcomes.\textsuperscript{84,85}

Bias based on difference between resting energy expenditure calculated from the equation and measured by indirect calorimetry, 95% coefficient of variation.

A = age in years; BSA = body surface area in m²; BW = body weight; HR = heart rate in beats/minute; Ht = height in cm; IC = indirect calorimetry; RR = respiratory rate in breaths/minute; T = temperature in degrees Celsius; Tmax = maximum body temperature in previous 24 hours in degrees Celsius; Wt = weight in kg; Ve = minute ventilation read from ventilator at time of measurement.
The low amount of nutrients actually provided with full feeding is alarming in some studies and raises the question of whether both groups were being underfed.\(^4^1,8^0\) A retrospective analysis of prospectively collected data for 475 patients requiring mechanical ventilation indicated that almost 40\% of patients received no more than 50\% of estimated nutritional requirements during the first 8 days in the ICU, and less than 15\% received 80\% or more of estimated requirements.\(^8^1\) In a study with 523 patients analyzing data for up to 7 days in the ICU, almost 33\% of the patients received less than 33\% of estimated requirements, and 67\% received no more than 65\%.\(^8^9\) Protein delivery, when evaluated, also tends to be poor; average protein intake of 0.7 g/kg/day has been reported.\(^4^1,8^0\) This is less than the 0.8 g/kg/day recommended for healthy adults and may be a contributing factor to poor outcomes.\(^8^2,9^1\) However, a 12-month follow-up of 510 surviving patients from the EDEN study found no difference in functional status for those receiving trophic feeding versus those receiving full feeding.\(^8^5,9^2\) All survivors showed significant impairments in physical, cognitive, and psychosocial functioning compared with population norms matched for age and sex; the physical function score at 12 months was 55 compared with 82 (p<0.001) but had improved from the 6-month assessment.

Canadian Clinical Practice Guidelines\textsuperscript{33,37,68,69}  

2003: Insufficient data except in severe head injury, where EN should be optimized to meet target dose  
2009: Upgrade to indicate achieving the target dose of EN should be considered in critically ill patients  
2013: Same as 2009 with the addition of patients with acute lung injury should NOT be considered for trophic feeds  

Hypocaloric feeding in patients who are not malnourished, receive some EN, or require PN < 10 days  
2007: Added insufficient data to make recommendation for hypocaloric PN in malnourished or obese patients, or when PN was needed > 10 days  

100\% measured or estimated calories  

ESPEN\textsuperscript{34,36}  

Poor performance in meeting nutritional goals with EN alone resulted in attempts to meet nutritional goals by adding supplemental PN when EN alone was inadequate. As reviewed earlier in this chapter, the benefit of added PN versus the risks does not have a definitive answer. It is unclear whether adding PN has adverse effects that counter the positive effects of more adequate nutrition in some patients but not others. There is almost certainly a complex interplay between several factors that determines which patients benefit from increased calorie provision and which do not. Unfortunately, available data are insufficient to devise a predictive algorithm or equation to assist the practitioner in identifying the patients who will benefit from aggressive nutrition.

**NUTRITION SUPPORT—MICRONUTRIENTS**

**Vitamins and Trace Elements**

There are no current guidelines for vitamin or mineral requirements in critically ill patients. Although evidence suggests that some vitamins
and minerals have increased requirements in critical illness because of increased metabolic demands, evidence is lacking to suggest that vitamins and minerals should be supplemented above physiologic amounts in critically ill patients. Enteral formulas supply the dietary reference intakes (DRIs), which includes recommended dietary allowances (RDAs) where these have been determined, at a certain volume, typically 1,000 mL. The DRI/RDA applies only to oral or enteral vitamins and minerals. If less than this amount is delivered to a patient daily, the patient will require additional vitamin and mineral supplementation. The parenteral multivitamins that are available in the United States provide fat-soluble vitamins at about the same dose as the DRI/RDA, even though there is a difference in oral and parenteral bio-availability. Water-soluble vitamins are provided at about 2.5–5 times the RDA in these multivitamin products. These doses have been used for 3 decades without reports of toxicity and allow for adequate dosing despite limited stability of some vitamins in PN. The increased doses provided parenterally will be enough to replete deficiencies or accommodate increased metabolic demands.

**Vitamin D**

Vitamin D deficiency is an emerging area of research in the ICU. Observational studies of non-ICU patients suggest that vitamin D has pleiotropic effects; hypovitaminosis D is implicated in musculoskeletal disorders, falls, altered immunity, infections, glucose intolerance, and cardiovascular disease. Serum 25-hydroxyvitamin D (25(OH)D) is typically ordered to assess vitamin D status, although specific guidelines for monitoring are still controversial. Although some sources recommend thresholds for vitamin D deficiency and insufficiency as less than 50 and 75 nmol/L, respectively, the IOM defines vitamin D deficiency and insufficiency as 30 and 50 nmol/L, respectively. The difficulty in monitoring vitamin D status during critical illness is caused by the effect of the systemic inflammatory response on serum or plasma concentrations. A prospective study from 2012 evaluated baseline vitamin D concentrations and followed subsequent daily vitamin D concentrations through 10 days after ICU admission. The
authors found that baseline levels decreased 3 days after admission and remained low while patients were in the ICU.\textsuperscript{96} Index of suspicion for deficiency is likely as good as 25(OH)D serum concentrations and more cost-effective when determining the need for supplemental vitamin D in critically ill patients.

Although 25(OH)D is measured to determine vitamin D status, 1,25-
dihydroxyvitamin D is the compound that has physiologic activity. Vitamin D refers to either ergocalciferol (vitamin D$_2$), which is consumed in the diet, or cholecalciferol (vitamin D$_3$), which is synthesized in the skin. The RDA for vitamin D was increased in 2010 from 200 international units to 400–800 international units, depending on age.\textsuperscript{93} Cholecalciferol and ergocalciferol are generally considered interchangeable, and oral supplements are available in both forms. However, some evidence suggests that cholecalciferol better increases vitamin D serum concentrations.\textsuperscript{93} No individual parenteral vitamin D product is available in the United States, and the adult parenteral multivitamin products contain only 200 international units. However, pediatric parenteral multivitamin products contain 400 international units per standard dose. With diligent attention to total amounts of all vitamins provided, use of a pediatric parenteral multivitamin could be considered for patients at high risk of complications from a true vitamin D deficiency (i.e., concentrations not influenced by systemic inflammatory response) when oral supplementation of vitamin D will not be possible for weeks to months.

Prospective studies evaluating vitamin D supplementation and patient outcomes in critically ill patients are rare. The VITdAL-ICU study evaluated 475 critically ill patients with 25(OH)D concentrations less than 20 ng/mL (50 nmol/L).\textsuperscript{97} This single-center double-blind study randomized patients to either placebo or vitamin D$_3$ orally or by nasogastric tube at a dose of 540,000 international units once,
followed by monthly doses of 90,000 international units for 5 months. There was no difference in the primary outcome of hospital LOS, nor was there any difference in secondary outcomes. The authors found a statistically significant decrease in hospital mortality among the subgroup of patients with 25(OH)D concentrations less than 12 ng/mL (30 nmol/L), but this disappeared at 6 months.

Data are insufficient to recommend vitamin D supplementation in critically ill patients.

**Vitamins C and E**

Decreased concentrations of vitamins C and E have been found in patients with burns, sepsis, trauma, and major surgery. With many vitamins, systemic inflammation is known to decrease vitamin concentrations, but unfortunately, few studies on vitamins C and E evaluate the presence of inflammation concomitantly. Supplementation of vitamins C and E is most often delivered as part of an antioxidant “cocktail” with selenium, or included in an immune-modulating enteral formula. However, the 2015 update of the Canadian Clinical Practice Guidelines added a new section regarding intravenous vitamin C, although evidence was insufficient to make a recommendation on supplementation of vitamin C in critically ill patients. The supplementation of antioxidants in critical illness is discussed later.

**Selenium**

Selenium is a trace element that is essential in many metabolic processes, including the enzymes glutathione peroxidase and selenoprotein P. Both enzymes are necessary for oxidative defense. Because selenium is classified as an essential trace element, it is added to enteral formulas and is included in five-ingredient multitrace additives for PN. Because of selenium’s role in antioxidant defense, it has also been studied at a supraphysiologic dose to improve outcomes in critically ill patients. Patients with sepsis and systemic inflammatory response have high selenium-dependent glutathione peroxidase activity and low selenium concentrations. Older guidelines recommend
intravenous selenium, primarily because of a small study published in 2007 and a meta-analysis from 2005, which showed potential benefit from doses of 500–1,000 mcg/day.\textsuperscript{32,37,69} The SIC (Selenium in Intensive Care) trial evaluated 249 patients with systemic inflammatory response, sepsis, and septic shock. Patients were randomized to receive 1,000 mcg intravenously of sodium selenite followed by 14 daily infusions of 1,000 mcg or placebo.\textsuperscript{100} The intention-to-treat analysis showed no significant difference in the primary outcome of 28-day mortality; however, the 92 per-protocol patients showed reduced mortality (p=0.49; OR 0.56; CI, 0.32–1.0).\textsuperscript{100} A meta-analysis published in 2005 aggregated seven studies with 186 patients and reported that selenium supplementation (alone and in combination with other antioxidants) was associated with a trend toward lower mortality (RR 0.59; 95% CI, 0.32, 1.08 p=0.09).\textsuperscript{101} For higher doses of selenium, one trial evaluating 60 patients with septic shock found no benefit in time to vasopressor withdrawal when 4,000 mcg was given on the first day and 1,000 mcg was given daily afterward for 9 days.\textsuperscript{102} A meta-analysis from 2012 aggregated 16 studies of critically ill patients and compared different dosing schemes used for selenium supplementation. Overall, the analysis found no mortality benefit to selenium in critically ill patients. When comparing selenium dosed at greater than 500 mcg, equal to 500 mcg, and less than 500 mcg daily, no dose achieved a statistically significant improvement in mortality.\textsuperscript{103} A separate meta-analysis from 2013 evaluated nine trials with 792 patients with sepsis only and found lower mortality (OR 0.73; 95% CI, 0.54, 0.98; p=0.03; $I^2 = 0\%$) with selenium supplementation than with placebo.\textsuperscript{104} In conclusion, given the available data, there appears to be no consistent benefit to supplementing supraphysiologic doses of selenium, and it cannot be recommended to routinely supplement selenium in critically ill patients.

Other Substances

Glutamine
Glutamine is an amino acid that has been studied in critically ill patients for more than 20 years. It is classified as conditionally essential in catabolic states. In critically ill patients, the main consumers of glutamine are macrophages and lymphocytes, which deplete glutamine stores in muscle tissues. Consequently, plasma glutamine concentrations fall. When this occurs, glutamine may be unavailable for immune cells and other rapidly dividing cells or the synthesis of glutathione, renal ammonia, and glycogen.

The practice of supplementing glutamine in critically ill patients has changed substantially as new studies have been published, which may serve as a cautionary tale for interpreting small studies. A small prospective cohort trial associated low plasma glutamine concentrations at ICU admission with increased hospital mortality in 2001. As a result, some clinicians began supplementing glutamine in critically ill patients. This was done either enterally (in doses of 0.16–0.5 g/kg of body weight per day) or parenterally (in doses of 0.18–0.57 g/kg/day), usually in combination with nutrition support.

A meta-analysis of smaller studies from 2002 found that critically ill patients given glutamine supplementation had a reduction in complication and mortality rates; the greatest benefit occurred in patients receiving high-dose, parenteral glutamine. The initial Canadian Clinical Practice Guidelines published in 2003 recommended supplementation of PN with parenteral glutamine, when available, but data were inadequate to make a recommendation on intravenous supplementation for patients receiving EN. Enteral glutamine was regarded as appropriate to consider in burn and trauma patients, but data were inadequate in other critically ill patients to suggest routine use. The nutrition guidelines for critically ill patients from SCCM/ASPEN, published in 2009, give a grade B and C recommendation to consider enteral and parenteral glutamine supplementation.

However, two subsequent larger trials failed to find a benefit to intravenous glutamine supplementation. The most recent and largest trials to date, the REDOXs and the METAPLUS trials, have actually found a signal of harm in supplementing glutamine to the
most critically ill patients. The REDOXs trial supplemented glutamine as 0.35 g/kg of ideal body weight per day intravenously and 30 g enterally per day. Patients enrolled in this trial were required to receive mechanical ventilation and have at least two organ system failures. The patients who received glutamine had a statistically significant increase in in-hospital and 6-month mortality.\textsuperscript{111} The METAPLUS study, in contrast, used enteral glutamine at a dose of 0.3–0.5 g/kg/day as part of an immune-modulating enteral product that also contained omega-3 fatty acids and antioxidants. These patients were mechanically ventilated with a maximum SOFA score of 12. In this trial, there was also a statistically significant increase in 6-month mortality for the patients who received glutamine supplementation.\textsuperscript{112}

These two studies differed in the route of administration and the dose of glutamine supplemented, but both found evidence of harm. The benefit seen previously was present in small single-center trials that were under-powered to detect an increase in mortality.\textsuperscript{113} After these studies were published, the Canadian Clinical Practice Guidelines 2013 updates added a caution for use of any glutamine in patients with shock or multiorgan failure.\textsuperscript{69} By the 2015 Canadian Clinical Practice Guidelines update, use of enteral glutamine was not recommended in critically ill patients.\textsuperscript{37} In conclusion, given the available evidence, it cannot be recommended to routinely supplement glutamine in critically ill patients.

**Arginine**

Arginine is another amino acid that has been studied for supplementation in critically ill patients. Soon after trauma or surgery, plasma arginine concentrations drop and remain low for days to weeks after the injury.\textsuperscript{114} Arginine is a substrate for nitric oxide production in several cell types, including T lymphocytes and myeloid cells. Physical injury causes myeloid-derived suppressor cells to appear; these cells express arginase-1, which leads to arginine deficiency and T-lymphocyte dysfunction.\textsuperscript{114-116} A recent meta-analysis that included about 3,000 patients found a treatment effect of arginine therapy, at doses delivered in immune-modulating enteral formulas of around 12
g/day, after major surgery; arginine treatment reduced risk of infection by 40% and overall LOS versus standard EN.\textsuperscript{115} However, the same may not be true in patients with sepsis. Most trials show very little benefit or, more commonly, harm when arginine is supplemented in patients with sepsis.\textsuperscript{117-119} The explanation for this effect may be the supraphysiologic supplement dose (8–20 g/day vs. 3–5 g/day normally ingested) promotes excessive nitric oxide, which worsens hypotension and may increase mortality.\textsuperscript{114,119,120} The 2009 SCCM/ASPEN guidelines recommended arginine supplementation as part of an immune-modulating enteral formula for patients with major GI surgery, trauma, burns, and head and neck cancers and for critically ill patients who were not severely septic.\textsuperscript{32} However, the Canadian Clinical Practice Guidelines have never recommended the use of arginine for critically ill mechanically ventilated patients.\textsuperscript{33,37,69,121} Because of the lack of high-quality studies supporting the use of arginine and the potential harm, it is not recommended to supplement arginine in critically ill patients.

**Antioxidants**

Antioxidants have been studied together with glutamine and/or arginine as part of an immune-modulating or immune-enhancing diet, but they have also been studied separately. Under normal physiologic conditions and inspiration of 21% oxygen, there are adequate defenses against reactive oxygen species and reactive nitrogen-oxygen species, commonly known as free radicals.\textsuperscript{122} Cellular injury occurs when the overproduction of free radicals overwhelms endogenous antioxidant defenses such as glutathione, superoxide dismutase, and antioxidant vitamins. Data have shown that in surgery, trauma, and sepsis, antioxidant levels are decreased and that the more severe the injury, the more depleted the antioxidant defenses become.\textsuperscript{101} The body’s antioxidant defense mechanisms depend on selenium, zinc, manganese, and iron, which are cofactors for antioxidant enzymes and the vitamins C, E, and beta-carotene. A recent meta-analysis pooled 21 randomized controlled trials with around 2,500 patients that
evaluated antioxidant supplementation in critically ill patients. Of note, this analysis excluded trials that also combined glutamine or arginine with antioxidant vitamins and trace elements. The authors found a decrease in overall mortality of 18% in the antioxidant-treated group (RR 0.82; 95% CI, 0.72–0.93; p=0.002). The analysis also noted a decrease in ventilator-days from a small group of included studies, and in the subgroup analysis of enterally versus parenterally supplied antioxidants, only the enteral route achieved a statistically significant benefit. Many of the studies performed with antioxidant supplementation have used slightly different doses of each antioxidant, though most include vitamins C and E and selenium, and the therapy ranges from 7 to 28 days, which should be considered when making a recommendation. Previous guidelines have recommended supplemental antioxidants for critically ill patients. Although the results from smaller studies and aggregated results from meta-analyses are promising, we do not yet know the optimal composition, dose, or route for supplementing antioxidants. Because of these unknowns, routine supplementation of antioxidants in critically ill patients cannot be recommended.

**Omega-3 Fatty Acids**

Another nutrient with the potential to affect immune function is the omega-3 fatty acids. Omega-6 fatty acids are metabolized into eicosanoids that tend to be proinflammatory; omega-3 fatty acids are metabolized into a different series of prostaglandins, leukotrienes, and thromboxanes that do not promote inflammation and thrombosis, and may be referred to as anti-inflammatory. In addition, when omega-3 fatty acids are incorporated into membrane phospholipids of immune cells, they alter membrane fluidity, which affects secondary messengers, transporters, receptors, and enzymes. Many studies have found a benefit with an omega-3–supplemented enteral formula (Oxepa) in patients with ALI or acute respiratory distress syndrome (ARDS) when compared to high-fat formulas, not typical ICU formulas. Use of omega-3–supplemented formulas will be
discussed in greater detail later. In addition, a recent meta-analysis concluded that critically ill patients who received enteral formulas with a high percentage of omega-3 fatty acids had decreased infectious rates, hospital LOS, and mortality. Although data suggest that parenteral omega-3 fatty acids are also beneficial, no products are currently approved for use in the United States. However, European intravenous omega-3 products can be obtained if an Investigational New Drug (IND) application is authorized for each patient by the U.S. Food and Drug Administration (FDA). Omega-3–containing enteral formulas are recommended for patients with ALI/ARDS, and recommendations for omega-3 fatty acid in other forms will change as products become available in the United States.

Probiotics

Probiotics have the potential to treat gut and immune disturbances in the critically ill population through competitively inhibiting the growth of pathogenic organisms, enhancing the mucosal barrier, and modulating the host inflammatory response. Understanding and modifying the human gut microbiome is still a developing area of research, and unfortunately, trials of probiotics in the critically ill population have not shown comprehensive benefit. Some studies have shown benefit, whereas others have shown no difference, likely because of differences between ICU populations and strains of probiotics used. The 2009 SCCM/ASPEN guidelines do not recommend providing probiotics to the general ICU population, but they do recommend probiotics for patients with transplantation, major abdominal surgery, and severe trauma (grade C). However, in light of conflicting evidence, the potential for harm, and the legal issues of providing non–FDA-approved products to hospitalized patients, use of probiotics in the critically ill population remains controversial.

ORGAN-SPECIFIC CONSIDERATIONS

Renal
Renal dysfunction is a common diagnosis in the ICU. Both acute kidney injury (AKI) and chronic kidney disease (CKD) affect a patient’s nutritional requirements and tolerance. To assess nutritional status, it is recommended to evaluate a patient’s weight and inflammatory status in setting nutritional goals.\textsuperscript{129} Indirect calorimetry is preferred to determine caloric needs in renal dysfunction. Protein goals, electrolyte provision, and vitamin/mineral needs depend on whether the patient is receiving renal replacement therapy and the type of therapy.

**Acute Kidney Injury**

Patients with AKI are both hypermetabolic and hypercatabolic as a result of the inflammatory response associated with acute injury.\textsuperscript{130} Metabolic complications that may occur in AKI include loss of glucose homeostasis, muscle wasting, protein catabolism, electrolyte imbalance, and development of metabolic acidosis.\textsuperscript{130} Protein catabolism causes accumulation of protein metabolism byproducts resulting in azotemia. Tissue catabolism also releases intracellular electrolytes such as potassium, phosphorus, magnesium, and protein-bound acids such as sulfuric acid and hydrochloric acid.\textsuperscript{131} This, combined with decreased renal clearance, leads to electrolyte imbalance and metabolic acidosis.

**Continuous Renal Replacement Therapy**

Continuous renal replacement therapy (CRRT) uses specialized filtration membranes that are highly permeable and that remove solutes by convection with or without diffusion. To discuss the implications of fluids used during CRRT, we will first discuss CRRT modalities. Continuous venovenous hemofiltration (CVVH), the most commonly used modality, uses convection to remove solutes and water. To prevent hypovolemia, water removed during hemofiltration must be returned to the patient as replacement fluid in the CRRT circuit. Conversely, continuous venovenous hemodialysis (CVVHD) uses dialysate to remove solutes. If the concentration in the dialysate is lower than the blood concentration, the solute is removed by diffusion;
If the opposite is true, the solute will be delivered to the patient. Continuous venovenous hemodialysis does not use replacement fluids in the circuit. Finally, continuous venovenous hemodiafiltration (CVVHDF) uses both dialysate and replacement fluids. Depending on the modality, CRRT dialysate fluids contain dextrose and either bicarbonate or lactate, and they may contain additional electrolytes. Dextrose amounts can vary in commercial CRRT dialysate solutions. Using a dialysate that contains just 1.5% dextrose at a flow rate of 1 L/hour can result in the patient’s receiving 500 dextrose calories from the CRRT alone.\(^{132}\) There are also disadvantages to using a dialysate with very low dextrose. Glucose losses may occur in the ultrafiltrate fluid removed during CRRT. Glucose losses into the dialysate are dependent on and are equal to the serum blood glucose concentration they are dialyzed against.\(^{133}\) Another source of calories from CRRT solutions is citrate, which is being used more commonly for anticoagulation during CRRT. In one study, a mean caloric load of citrate anticoagulation during CRRT was 1,323 calories per day.\(^{134}\) At a CVVHDF flow rate of 2 L/hour, another study found a caloric load of 63 calories/hour with a 2.2% citrate solution, 20 calories/hour with a 4% trisodium citrate solution, and 60 calories/hour with heparin anticoagulation.\(^{135}\)

Continuous renal replacement therapy dialysate solutions may contain electrolytes, and all replacement fluids should contain dextrose, sodium, chloride, potassium, calcium, and magnesium. Occasionally, dialysate fluids are also used as replacement fluids. Of special note, phosphorus cannot be added to a calcium-containing CRRT solution, so frequent monitoring and replacement of phosphorus is prudent.

Protein needs are elevated for patients with AKI receiving CRRT, largely because of the severity of their illness and the accompanying inflammatory response. In addition, small proteins and amino acids are lost through CRRT. Studies have shown that at least 1.5 g/kg/day of protein is needed daily, and up to 2.5 g/kg/day may be required for positive nitrogen balance.\(^{129}\) An amino acid solution is available for use in PN formulas for patients with AKI; however, evidence is insufficient to support its use, and current guidelines recommend a standard amino
acid solution.\textsuperscript{129} Patients receiving CRRT do not usually require fluid restriction, so concentrated enteral or parenteral formulas are not necessary.

If a patient receiving CRRT requires enteral feeding, the recommendation is to start with a standard enteral formula and to follow standard ICU calorie and protein requirements. If significant electrolyte disturbances occur, a formula designed for renal failure with lower electrolyte provision may be considered.\textsuperscript{129} However, high hemofiltration rates increase the removal rate for small molecules like electrolytes, so patients receiving CRRT do not typically require lower amounts of electrolytes while the CRRT is being used. If a patient is receiving PN while on CRRT, electrolytes may require frequent adjustment, so clinicians may prefer to minimize electrolytes in the PN solution and adjust by CRRT fluids or replace outside the PN.

\textbf{Chronic Kidney Disease}

Patients with preexisting CKD may require nutrition support in the ICU. Patients with CKD develop protein energy wasting as a result of neuroendocrine factors that include reduced protein synthesis and increased protein breakdown. Many patients also have glucose intolerance and hypertriglyceridemia. Altered calcium/phosphorus metabolism and anemia should be considered when prescribing nutrition. Finally, because of decreased renal clearance, patients with CKD will also have impaired clearance of electrolytes, metabolic acidosis, and altered fluid status.

Restricted protein diets have long been used and advocated for delaying the progression to dialysis.\textsuperscript{133,136-138} These studies typically targeted a protein goal of 0.6 g/kg/day or less of protein. However, while these patients are acutely ill and hospitalized, catabolism will increase protein requirements, and patients may require dialysis to aid in removal of metabolic wastes.\textsuperscript{129} Patients should be prescribed protein that meets their needs according to degree of critical illness.

\textbf{Hemodialysis}
Energy requirements for patients receiving hemodialysis are similar to those for patients without renal failure. The current protein recommendation for patients with CKD on maintenance hemodialysis is 1.2 g/kg/day; however, in critical illness, protein should be provided according to critical care guidelines, 1.0–2.5 g/kg/day, to meet increased metabolic demands. Vitamin status is an additional concern. Hemodialysis removes water-soluble vitamins, including vitamin C, pyridoxine (B₆), cyanocobalamin (B₁₂), thiamine (B₁), and folic acid, as well as vitamin D. A standard oral renal vitamin may be used to replace these if the patient has oral or enteral access.

**Peritoneal Dialysis**

Calories from the dextrose-containing peritoneal dialysis solutions may be as high as 500–1,000 calories per day and should be accounted for when designing the nutrition prescription. Wideroe et al. have developed a system to estimate the amount of absorbed glucose from the peritoneal dialysis solution. As with other CRRT modalities, calorie and protein goals in critical illness should be set to goals according to the patient’s level of catabolism.

**Respiratory**

In the past, high lipid feedings were recommended for patients with respiratory compromise. The theory behind this practice was that using lipids for calories produces less carbon dioxide than carbohydrates or protein and therefore will aid in weaning from the ventilator or improving respiratory status. This is represented as a respiratory quotient (RQ) equal to carbon dioxide production (Vco₂) divided by oxygen consumption (Vo₂), with an RQ from lipid oxidation being 0.85, protein 0.82, and carbohydrates 1. However, early reports of respiratory dysfunction and failure with high-carbohydrate feedings provided excessive calories overall. A study by Talpers et al. shows this; 20 mechanically ventilated patients received a low, medium, or high proportion of carbohydrates in enteral feeding or 1.0, 1.5, or 2.0 times
their basal energy expenditure in total calories. There was no difference in Vco₂ between the different carbohydrate feedings, but the Vco₂ significantly increased as total calories increased.\textsuperscript{141} This classic study supports the argument, and current practice, that limiting total calories will do more to prevent ventilatory adverse effects than limiting carbohydrates or increasing lipids.

Both ALI and ARDS have an inflammatory component. In both conditions, eicosanoid-mediated neutrophil migration into the alveolar space causes lung damage.\textsuperscript{127,142} The type and activity of eicosanoids can be modified by omega-6 or omega-3 fatty acids. In addition, \( \gamma \)-linolenic acid (GLA) decreases neutrophil leukotriene synthesis and increase prostaglandin E₁, which may be beneficial in ALI/ARDS.\textsuperscript{141} Table 4.5 compares studies evaluating omega-3–supplemented EN in patients with ALI/ARDS.

Many clinical trials using an enteral formula supplemented with omega-3 fatty acids, GLA, and antioxidants (Oxepa) have shown benefit in patients with ALI/ARDS.\textsuperscript{125-127,143} One study found a mortality benefit in the supplemented group compared with the group receiving the high-fat control formula.\textsuperscript{143} Limitations of these studies include small patient numbers, use of a high-fat comparator, and heterogeneous etiology/severity of ALI/ARDS in included patients, although patients with a diagnosis of ALI/ARDS are inherently heterogeneous. The largest study to date found no benefit to supplementing with omega-3s, GLA, and antioxidants; this study used a twice-daily enteral supplement (not the commercially available Oxepa formula) to bolus the nutrients and used a high-carbohydrate control formula, unlike previous studies.\textsuperscript{142} Further large studies using typical ICU formulas rather than high-fat formulas are needed to determine whether these nutrients can be bloused separately from the enteral formula or whether they need to be given continuously to be beneficial. No studies have shown increased adverse events with omega-3–supplemented EN compared with the control formula.\textsuperscript{125-127,142,143} With the mixed data available, some clinicians choose to recommend an enteral formula supplemented with omega-3 fatty acids, GLA, and antioxidants Oxepa for patients with ALI/ARDS, whereas others do not.
Hepatic

Patients with advanced hepatic failure represent a challenge in nutritional assessment and delivery. Many patients with chronic liver disease are malnourished, but available tools for assessment may be inaccurate. Malnutrition occurs in most patients with alcoholic liver disease, but it may be less common in patients with non-alcoholic steatohepatitis.\(^\text{144}\) Body weight and fluid distribution is altered in patients with cirrhosis, and many patients have hypoalbuminemia and decreased concentrations of other blood proteins. Providing nutrition support to patients with liver disease is challenging. The liver is responsible for the metabolism of proteins, carbohydrates, and lipids. Altered protein metabolism is a well-known sign of advanced liver disease. These patients have low plasma concentrations of the branched-chain amino acids (BCAAs); leucine, valine, and isoleucine; and high concentrations of aromatic amino acids. In healthy patients, BCAAs are taken up by skeletal muscle to create glutamine, a carrier for ammonia, or are transported to the liver for gluconeogenesis. In patients with cirrhosis, excessive glutamine is produced in the muscle while the liver is unable to convert ammonia to urea, resulting in increased concentrations of ammonia.\(^\text{145}\) Patients with cirrhosis also have glucose intolerance and insulin resistance. This is associated with the early use of protein and lipid for fuel.\(^\text{145}\) Finally, patients with advanced liver disease also have impaired lipid metabolism. Altered absorption is caused by decreased concentrations of intraluminal bile salts, concurrent pancreatic or intestinal disease, and mucosal edema. In addition, there is an imbalance between triglyceride synthesis and catabolism, which depletes lipid stores.\(^\text{145}\)

| Table 4.5 | Comparison of Studies Evaluating Omega-3–Supplemented EN in Patients with ALI/ARDS |
ARDS = acute respiratory distress syndrome; BID = twice daily; DHA = docosahexaenoic acid; EPA = eicosapentaenoic acid; Fio\(_2\) = fraction of inspired oxygen; ITT = intention-to-treat analysis; LIS = lung injury score; PEEP = positive end-expiratory volume; PP = per-protocol analysis; RR = relative risk; SOFA = Sequential Organ Failure Assessment (score).

Caloric requirements for these patients may be difficult to ascertain. The Harris-Benedict equation is inaccurate in patients with cirrhosis.\(^{146}\) Anthropometry, 24-hour urinary creatinine collection, and SGA will yield more accurate information about the patient’s nutritional status.\(^{147}\) Although there may be a theoretical basis to consider restricting protein in patients with liver disease, this is not necessary. A study by Cordoba et al. showed that hepatic encephalopathy developed at a similar rate...
In patients given either a low-protein or a standard-protein formula.\textsuperscript{148} In addition, Gheorghe et al. found that when patients with cirrhosis were given an oral diet with standard calories and protein, their hepatic encephalopathy improved, with the greatest improvement occurring in the most severe patients.\textsuperscript{149} Critically ill patients should receive the amount of protein that meets their catabolic needs (1.5–2.0 g/kg/day). Stable or less critically ill patients with liver disease require 1–1.5 g/kg/day of protein.

The preferred route for nutrition support in patients with liver disease is the enteral route. Enteral supplementation in these patients improves nutritional status and, in some cases, markers of hepatic function.\textsuperscript{149-152} The enteral route is preferred because of the infection risk with a central vascular line and preservation of gut mucosa and accompanying decreased risk of bacterial translocation.\textsuperscript{145} In addition, PN can cause liver damage in the long term and, in some cases, with short-term use. Fear of bleeding in patients with esophageal varices may delay placement of nasoenteric feeding tubes. However, small-bore soft-tipped nasally or orally placed tubes have a low risk of causing bleeding in non-bleeding varices, and placement should not be delayed or deferred.\textsuperscript{153} After variceal hemorrhage, however, it may be advisable to wait 48 hours after bleeding has been stopped before resuming feeding.\textsuperscript{153}

Standard enteral formulas should be used for critically ill patients with liver disease. Some outpatient studies suggest that oral supplementation with BCAAs delays progression of liver disease. No studies show that short-term supplementation has any benefit in the critically ill population. The current guidelines recommend reserving formulas with BCAAs for the rare patient with hepatic encephalopathy who is refractory to medical treatment.\textsuperscript{32}

Other nutritional considerations for patients with liver disease include vitamins and electrolytes. Vitamin D deficiency is common in patients with liver disease, especially cholestatic liver disease, so monitoring and replacement is important in these patients.\textsuperscript{145} Thiamine deficiency and refeeding syndrome may be common in patients with liver disease who continue to consume alcohol.\textsuperscript{145,154} Another important
consideration is to restrict sodium to 2 g daily in patients with ascites.

In summary, it may be difficult to assess critically ill patients with acute or chronic liver disease for malnutrition, but malnutrition is common in these patients. Calorie and protein goals should be provided to meet the catabolic needs of critical illness, with care not to restrict protein. Special amino acid preparations containing high amounts of branched chain amino acids are not necessary, except for patients with hepatic encephalopathy refractory to lactulose and luminal antibiotics. Vitamin D and electrolytes should be monitored.

Pancreatic

Nutrition support may be required for patients who have either acute pancreatitis or a history of chronic pancreatitis. The main nutritional considerations in acute pancreatitis are hypermetabolic/hypercatabolic state, hyperglycemia, hypertriglyceridemia, and hypocalcemia. Nutritional considerations for chronic pancreatitis include anorexia, weight loss, exocrine insufficiency, and malabsorption. We will discuss the primary issues in patients with pancreatic disease, including timing and type of nutrition support initiation and pancreatic enzyme replacement.

Route and Type of Feeding

The discussion of pancreatic rest in acute pancreatitis and its implications for nutrition support has changed dramatically in the past 20 years. In the past, many clinicians considered pancreatic rest synonymous with bowel rest, and patients were placed on PN in an effort to decrease complications. Providing pancreatic rest as a sole management strategy does not improve patient outcome.\textsuperscript{155} Enteral nutrition is superior to PN, especially in patients with severe acute pancreatitis.\textsuperscript{156-159} In one study where 100\% of the enrolled patients had severe acute pancreatitis, overall and septic complications were significantly reduced.\textsuperscript{159} Evidence is still insufficient to show the superiority of EN to a standard oral diet, although smaller studies suggest it.\textsuperscript{160} Many trials evaluating the safety of EN in severe acute
pancreatitis used jejunal tube placement to avoid gastric stimulation.\textsuperscript{161} Although fewer studies support gastric feeding over jejunal feeding, the American College of Gastroenterology and SCCM/ASPEN guidelines recommend gastric and jejunal feeding equally.\textsuperscript{32,162} Standard polymeric formulas should be the first choice for enteral feeding.\textsuperscript{155} If the patient has increased nausea or increased abdominal pain, the tube position should be checked or advanced distally to the jejunum, the patient switched to continuous enteral feeding, or the feeding changed to a semi-elemental or elemental formula.\textsuperscript{32} Increased nausea is not a contraindication to continuing EN.

If a patient develops persistent ileus or bowel obstruction, PN may be considered after 5 days of admission. Because intravenous lipids do not worsen symptoms of pancreatitis, they can be safely used when serum triglyceride is below 400 mg/dL.\textsuperscript{155} Standard guidelines apply to formulating PN for patients with acute pancreatitis.

**Enzyme Replacement**

Pancreatic enzyme replacement will be necessary for many patients with chronic pancreatitis. Recently, the FDA required all manufacturers of pancreatic enzyme supplements to submit an NDA by April 2010 or to stop distributing their products. Before this, there were around 25 pancreatic enzyme products, and because this deadline has passed, there are six pancreatic enzymes on the U.S. market: Creon, Zenpep, Pancreaze, Ultresa, Viokace, and Pertzye. Each product has several strengths with differing amounts of amylase, lipase, and protease. Viokace is the only product without an enteric coating and is labeled to take with a proton pump inhibitor. Labeled dosing for all products recommends dosing according to the Cystic Fibrosis Foundation, beginning with 500 units of lipase per kilogram per meal and titrating to a maximum of 2,500 lipase units per kilogram per meal. Many other dosing schemes are available.\textsuperscript{155} Although none of the available products are labeled for administration through gastrostomy or distal feeding tubes, dosing and administration methods have been reported in the literature. One method is to provide 1,000 lipase units for each gram of fat provided by the enteral feed and dose this every 3 hours.
for continuous feeding.\textsuperscript{163} For gastric tubes, it is recommended to suspend enteric-coated microspheres (all products except Viokace) in a nectar thick acidic liquid and administer by syringe into the feeding tube.\textsuperscript{163} For distal feeding tubes, the enteric-coated spheres must be mixed with sodium bicarbonate to activate the enzymes, which may take more than 30 minutes.\textsuperscript{163,164} The only products found to dissolve completely in sodium bicarbonate within 30 minutes, dosed in lipase units, are Creon 24,000, Ultresa 23,000, and Zenpep 20,000 and 40,000.\textsuperscript{164} Water, carbonated beverages, or sweetened beverages should not be used to dilute pancreatic enzymes because this increases the adhesiveness of the enteric coating, which can cause tube obstruction. Crushing the microspheres is not recommended because this causes coagulation of the formula, and the powder can potentially be inhaled or come into contact with the eyes. It is not recommended to add pancreatic enzymes directly to the enteral feeding because this may compromise sterility and will cause coagulation of the formula, which may cause clogging. Table 4.6 summarizes information on pancreatic enzyme administration with EN.

In conclusion, patients with severe acute pancreatitis should receive nutrition support by the enteral route whenever possible. Enteral feeding is associated with not only an improvement in nutritional status but also a reduction in complication rates. Patients with acute pancreatitis may be fed by either the gastric or the jejunal route. If a critically ill patient requires pancreatic enzyme replacement, the pharmacist should be aware of new formulations and dosing strategies.

\textbf{DISEASE-SPECIFIC CONSIDERATIONS}

\textbf{Diabetes/Glucose Control}

A recent survey of U.S. hospitals reported that hyperglycemia occurred in 46\% of critically ill patients.\textsuperscript{165} Hyperglycemia has been associated with many poor outcomes in critically ill patients, including infections, septic shock, poor wound healing, and increased ICU stay.\textsuperscript{166} Both hyper- and hypoglycemia should be avoided in critically ill patients.
Current ASPEN guidelines recommend a blood glucose target of 140–180 mg/dL in adult critically ill patients receiving nutrition support. This recommendation is in line with the current AACE/ADA (American Association of Clinical Endocrinologists/American Diabetes Association) recommendations for critically ill patients. Avoiding overfeeding is critical in patients with hyperglycemia; excess calories can contribute to hyperglycemia and associated poor outcomes. All sources of calories should be included in the nutritional assessment, including propofol and dextrose-containing intravenous fluids.

Either standard or specialized diabetes/hyperglycemia enteral formulas are appropriate for critically ill patients with hyperglycemia. Many clinicians choose specialized formulas because of a lower provision of glucose and a relatively high provision of protein, which is needed for critical illness. Continuous enteral feeding is more commonly tolerated with less variation in serum glucose. Serum glucose should be monitored as enteral feeding is advanced to goal rate, and intravenous insulin infusions may be necessary.

If PN is necessary in a patient with hyperglycemia, it is prudent to begin insulin therapy before or concurrently with PN and/or to reduce dextrose in the PN. Parenteral nutrition is associated with greater hyperglycemia than EN. Initially, intravenous insulin infusion that may be titrated separately from the PN infusion is recommended; if the infusion is to be discontinued, 80% of the daily dose from the infusion may be added to the PN. Another strategy for estimating the insulin requirements to be added to PN is to add 0.05–0.1 unit of regular human insulin per gram of dextrose in the PN. It is best to be conservative when estimating insulin requirements in PN because most facilities prepare PN solutions 12–24 hours before they are administered, and changing insulin requirements can be difficult to predict. Additional subcutaneous insulin may be needed for unexpected hyperglycemia.

Table 4.6  Pancreatic Enzyme Administration with EN
Thermal Injury

Burn injuries result in a hypermetabolic state similar to trauma or sepsis. The degree to which patients with severe burns are hypermetabolic and hypercatabolic is much greater, however. Because of the hypermetabolic nature of burn injuries, the resting energy expenditures of pediatric patients with severe burns have been reported to be up to 150% greater than expected and up to 160% greater in adults. In addition, patients with burns may oxidize amino acids at a rate 50% higher than fasting controls, leading to a significant protein deficit. This significant calorie and protein hyper-metabolism may continue for up to 2 years post-injury. If nutritional interventions are not made, significant weight loss can occur. A 10% loss of total body mass in patients with burns leads to immune dysfunction; 20%, to impaired wound healing; 30%, to severe infections; and 40%, eventually to death. Time to receipt of EN is critical to lessen the impact of the hypermetabolic state through modulation of catecholamine concentrations and maintaining gut mucosal integrity. Early enteral feeding initiated less than 24 hours after injury is recommended. Parenteral nutrition should only be used if the patient has a non-functional GI tract; it is unclear whether PN should be used.
in addition to EN when calorie and protein goals cannot be met with EN alone.

Indirect calorimetry is the most reliable way to measure caloric needs in patients with severe burns. If indirect calorimetry is not available, predictive equations may be used. Some authors suggest the Galveston, Curreri, or Toronto equations,\textsuperscript{167} whereas others suggest that the Milner and Carlson equations are most accurate.\textsuperscript{169} Overall, it can be expected that the caloric requirements of these patients will be higher than in patients without burns. The next nutritional consideration is the balance of substrates to provide.

Patients with severe burns will have high caloric requirements, so it is important to provide glucose at less than the maximum glucose oxidation rate (7 mg/kg/hour). High-carbohydrate formulas are typically provided to patients with burns because this has been associated with improved outcomes.\textsuperscript{168} Conversely, insulin therapy is used at some burn centers for purposes other than glucose control. Typically, this is done with continuous infusions of insulin and dextrose titrated to euglycemia. Insulin therapy in patients with burns stimulates muscle protein synthesis, increases lean body mass, and is associated with improved wound healing, without increasing hepatic triglyceride production.\textsuperscript{167}

Immediately after burn injury, fat metabolism and use are altered. There is an increase in peripheral fat breakdown and use by the liver. About 30\% of the available free fatty acids are used for fuel through beta-oxidation; the rest undergoes reesterification and potential accumulation in the liver.\textsuperscript{167} Some centers may therefore limit fat administration to the minimal amount needed to prevent essential fatty acid deficiency.

Increased proteolysis is an important metabolic implication of burns. Protein requirements are estimated at 1.5–2 g/kg/day in adults with burns and at 2.5–4.0 g/kg/day in children with burns.\textsuperscript{32,167} Some clinicians advocate the use of the amino acid glutamine for patients with burns. The 2009 SCCM/ASPEN guidelines recommend immune-modulating enteral formulas that contain glutamine for patients with burns, as well as enteral supplementation.\textsuperscript{32}
Certain vitamins and minerals are also recommended for patients with burns. Decreased vitamin and mineral concentrations are associated with poor outcome; however, further research is needed to determine the dosages for these micronutrients. An older study recommends the following daily for patients with greater than 20% total body surface area burns: one multivitamin, 500 mg of ascorbic acid twice daily, 10,000 international units of vitamin A, and 45–50 mg of zinc.\textsuperscript{170} European guidelines recommend supplementation of vitamin C, copper, selenium, and zinc.\textsuperscript{171} Recently, low vitamin D concentrations were reported in children with burns despite supplementation, but the significance of this is not yet known.

In summary, patients with severe burns are highly catabolic. These patients will have high caloric and protein needs immediately post-burn and potentially long after the initial injury. Protein requirements are estimated at up to 2 g/kg/day for adults and up to 4 g/kg/day for children with severe burns. Early enteral feeding is preferred; a formula with a high carbohydrate to fat proportion is a reasonable choice. Patients with severe burns should receive the RDA of necessary vitamins and minerals at a minimum and may require additional supplementation.

**SUMMARY**

Critically ill patients are characterized by an inflammatory response that results in a failure to adapt energy and protein use to restore homeostasis, as occurs in simple starvation. The complexities of nutrition support are many in this population, and there are several controversies with few definitive answers regarding the optimal nutrition therapy for best outcomes. However, nutrition support therapy in critically ill patients is a rapidly evolving aspect of patient care with many new studies being conducted. Practitioners must remain cognizant of emerging data, and studies must be evaluated carefully to determine the study population, including severity of illness and nutritional status, and applicability of results to an individual patient. Until more robust data are available, clinical practice guidelines will
continue to guide clinicians in their selection of nutrition support therapy but cannot determine the most appropriate therapy for any individual patient.

LEARNING OBJECTIVES

1. Describe sources of hyperglycemia in critically ill patients.

2. Critique primary literature and multidisciplinary guidelines on glucose management in the intensive care unit.

3. Analyze medication therapy options for glucose management in a critically ill patient.

4. Categorize and construct treatment plans for patients with hyperglycemic emergencies (diabetic ketoacidosis and hyperglycemic hyperosmolar state).

5. Formulate a plan for an institution-wide multidisciplinary approach to glucose management.

ABBREVIATIONS IN THIS CHAPTER

BG  Blood glucose
DKA  Diabetic ketoacidosis
INTRODUCTION

Management of blood glucose (BG) in critically ill patients is one of the key facets of supportive care. Retrospective analyses have shown increased mortality and morbidity with dysglycemia.\textsuperscript{1-5} In this chapter, we will review the causes of hyperglycemia in the critically ill population as well as in the primary literature focused on glucose management in the intensive care unit (ICU) population. We will also evaluate medication therapy options for patients with hyperglycemia, as well as for patients undergoing a hyperglycemic emergency such as diabetic ketoacidosis (DKA) or hyperglycemic hyperosmolar state (HHS).

PATHOPHYSIOLOGY/CAUSES OF HYPERGLYCEMIA

Several mechanisms are responsible for acute hyperglycemia in ICU patients. These include insufficient antihyperglycemic therapy in patients with a known history of diabetes because many patients with diabetes on oral agents have their oral agents discontinued on admission, which are not replaced with an effective inpatient antihyperglycemic regimen.\textsuperscript{6} Critically ill patients also commonly have increased insulin resistance among peripheral tissue, and increases in both hepatic and renal gluconeogenesis.\textsuperscript{7} Acute hyperglycemia related
to critical illness, also called stress hyperglycemia, is caused by release of the hormones norepinephrine, epinephrine, cortisol, and growth hormone and increases in the inflammatory mediators that lead to insulin resistance.\(^8\) Hyperglycemia can increase proinflammatory cytokines, prothrombotic mediators, and oxidative stress.\(^9\) External factors potentially contributing to hyperglycemia are the use of dextrose-containing intravenous admixtures and maintenance fluids as well as nutrition with high-carbohydrate tube feedings.\(^6\) Hyperglycemia can also impair blood flow and cause decreased perfusion in patients with acute coronary syndromes.\(^10\)

The deleterious effects of hyperglycemia are well documented in many organ systems throughout the body, and as such, it is important to address glucose status in all ICU patients. We will discuss the benefits to glucose management shown in the primary literature later in this chapter.

---

**RANDOMIZED CONTROLLED TRIALS: TIGHT VS. MODERATE GLUCOSE MANAGEMENT**

Ideal goal BG concentrations for critically ill patients remain a topic of controversy. In this section, we will review the primary literature comparing “tight” BG control with “moderate” BG control in the ICU.

**Leuven SICU**

A 2001 Belgian single-center, nonblinded, randomized controlled trial (RCT) of 1,548 patients, known as the Leuven SICU trial by Van den Berghe et al., compared treatment of surgical intensive care unit (SICU) patients with intensive or conventional glycemic control.\(^11\) Most patients in this analysis were post-cardiac surgery (63% in the conventional arm and 62% in the intensive arm). This was the first large trial to show a decrease in morbidity and mortality associated with tight glycemic control in the ICU. The intensive arm aimed for a goal glucose of 80–110 mg/dL, whereas the conventional glycemic control arm treated patients to a goal glucose of 180–200 mg/dL. For the primary
end point of mortality, a significant reduction was noted in the intensive arm (4.6% vs. 8%; p<0.04). Secondary outcomes that improved in the intensive glycemic control arm included in-hospital death (7.2% vs. 10.9%; p=0.01) and in-hospital death among those in the ICU for more than 5 days (16.8% vs. 26.3%; p=0.01). The increased mortality in the conventional arm can likely be attributed to the increased morbidity in several categories compared with the intensive glycemic control arm: need for renal replacement (8.2% vs. 4.8%; p=0.007), septicemia (7.8% vs. 4.2%; p=0.003), median number of red blood cell transfusions per patient (2 vs. 1; p<0.001), and polyneuropathy (51.9% vs. 28.7%; p<0.001). Hypoglycemia defined as a glucose value less than 40 mg/dL was increased in the intensive arm (5.1% vs. 0.8%; p<0.001).

Leuven MICU

Investigators tried to replicate the results of the SICU trial in the medical intensive care unit (MICU) at the same center. Twelve hundred MICU patients were randomized to either intensive or conventional arms with identical goals. There was no significant difference in the primary end point of in-hospital mortality, which was 40.0% in the conventional treatment group versus 37.3% in the intensive treatment group (p=0.33). However, for patients who stayed in the ICU for 3 days or more, in-hospital mortality was reduced in the intensive insulin therapy arm (52.5% vs. 43%; p=0.009).

Significant differences in morbidity occurred in all patients receiving intensive insulin therapy (newly acquired kidney injury: 5.9% vs. 8.9%; p=0.04; earlier weaning from mechanical ventilation with intensive insulin therapy: hazard ratio 1.21; 95% confidence interval [CI], 1.02–1.44; p=0.03), with earlier discharge from the ICU (p=0.04) and the hospital (p=0.05). In the subgroup of patients in the ICU for more than 3 days, intensive insulin therapy compared with conventional therapy had a similar morbidity benefit between arms in accelerated weaning from mechanical ventilation (p<0.001), discharge from the ICU (p=0.002), and discharge from the hospital (p<0.001).
There was no difference in the need for new renal replacement therapy between arms, though fewer patients in the intensive treatment arm acquired kidney injury, defined as a serum creatinine doubling that at presentation (12.6% vs. 8.3%; p=0.05), and fewer patients in the intensive arm reached a peak serum creatinine concentration greater than 2.5 mg/dL (39.4% vs. 32.5%; p=0.04). Hyperbilirubinemia was also reduced in the intensive treatment group (55.2% vs. 47.3%; p=0.04). Hypoglycemia (less than 40 mg/dL) occurred more often in the intensive treatment arm (18.7% vs. 3.1%; p<0.001).

**VISEP Trial**

Brunkhorst et al. assessed intensive insulin therapy compared with conventional insulin therapy in severe sepsis in a multicenter, open-label, 2 × 2 factorial design that also randomized patients to receive 10% pentastarch or modified Ringer lactate.\textsuperscript{13} The Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP) trial recruited patients in 18 academic medical center ICUs within 24 hours of ICU admission. The intensive insulin therapy arm was suspended prematurely after a safety analysis of 537 patients showed an increase in hypoglycemia (less than 40 mg/dL) in the intensive insulin therapy group (17% vs. 4.1%; p<0.001). No significant difference between mortality and SOFA (Sequential Organ Failure Assessment) scores was noted between the intensive and conventional insulin therapy arms.

**Glucontrol**

In an attempt to replicate the results of the Leuven trials in a multicenter study, Preiser et al. published the Glucontrol study in 2009.\textsuperscript{14} Glucontrol was initially designed to enroll 3,500 patients at 19 MICUs and SICUs into either an intensive (80–100 mg/dL) or a conventional (140–180 mg/dL) glycemic control arm. The trial was terminated early after randomizing only 1,101 patients after a high rate of unexpected protocol violations were detected. The intention-to-treat population that was evaluated for ICU mortality showed no significant
difference, though the study was underpowered. As in previous trials, intensive insulin therapy was associated with significantly higher hypoglycemia (8.7% vs. 2.7%, p<0.001).

A post hoc analysis of the Glucontrol trial showed an increased odds ratio of survival in patients who had achieved at least 50% of cumulative time with BG at a goal of 80–100 mg/dL, though no significant differences in rate or severity of organ dysfunction were seen.¹⁵ Given the methodological flaws of the study and the lack of protocol adherence, these findings should be hypothesis generating for future analyses of tight glucose control.

**NICE-SUGAR Trial**

The largest randomized trial to date comparing glycemic targets was the Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial.¹⁶ In this study, 6,104 MICU and SICU patients with an expected ICU length of stay of 3 or more days were randomized to intensive (81–108 mg/dL) or conventional (140–180 mg/dL) glycemic control arms. No difference in mortality occurred at 28 days; however, at 90 days, mortality was increased in the intensive treatment arm (27.5% vs. 24.9%; p=0.02).

Unlike the prior two Leuven trials from Van den Berghe and colleagues, no notable differences in morbidity were seen despite the increase in mortality in the NICE-SUGAR analysis. No significant differences between arms were seen when comparing days on mechanical ventilation, positive blood culture, use of renal replacement therapy, or red blood cell transfusion.

A BG value of 40 mg/dL or less was seen more often in the intensive insulin therapy arm (6.8% vs. 0.5%; p<0.001). A post hoc analysis found an increased incidence of death in either arm (in patients whose death was not attributable to respiratory, arrhythmia, or neurologic causes) associated with severe (less than 40 mg/dL) hypoglycemia (p=0.002).¹⁷ In the subgroup of patients with death from distributive shock, a significant correlation was seen with both moderate hypoglycemia (40–70 mg/dL) and severe hypoglycemia (p<0.001).
Because the analysis was conducted post hoc, a causal relationship with hypoglycemia and mortality cannot be established.

**Meta-analyses**

Griesdale and colleagues published a meta-analysis that included 26 trials and 13,567 patients. Although 26 studies were included, the five studies discussed in detail earlier accounted for 10,406 (76.7%) of the evaluated patients.

No significant difference in mortality was seen in any of the patients. When evaluating specific cohorts, patients in SICUs had decreased mortality when treated with intensive insulin therapy compared with standard therapy (7.4% vs. 11.8%; relative risk [RR] 0.93; 95% CI, 0.83–1.04); however, no mortality difference was seen in other ICUs. Rates of hypoglycemia were significantly increased in patients treated with intensive insulin therapy compared with the control arms (10.7% vs. 1.6%; RR 5.99; 95% CI, 4.47–8.03).

The authors concluded that intensive insulin therapy increased the risk of hypoglycemia without a benefit in mortality in the critically ill population; however, patients treated in SICUs may benefit from intensive insulin therapy.

**Summary of the Primary Literature in Critically III Glucose Management**

Randomized assessments of intensive versus conventional glucose management in critically ill populations provided mixed results. The most polarizing result, which remains under debate, is whether either an increase or a decrease in mortality is seen with intensive insulin therapy to a BG of 80–110 mg/dL, or whether any difference between the two interventions exists. The most likely cause for the variability in results is the heterogeneity of the patients, interventions, and statistical analysis of the trials. Table 5.1 highlights notable differences that may have affected the investigators’ findings. The Leuven SICU trial’s sample size was about one-fourth that of the NICE-SUGAR analysis,
though the Leuven SICU enrolled more than 99% of the patients screened, whereas NICE-SUGAR’s analysis ultimately excluded 85% of the patients screened. The patients in the Leuven SICU were predictably less sick than the patients in the Leuven MICU trial as well as in the analyses conducted in mixed ICUs, as evidenced by their lower Acute Physiology and Chronic Health Evaluation II (APACHE II) scores and mortality rates.

Nutritional support was provided parenterally in 85% of patients in both Leuven trials, compared with only 25% of patients in the NICE-SUGAR analysis, not only serving as a distinct display of different national standards of care, but also calling into question whether there was a difference in the amount of glucose in the form of nutrition supplied to patients who were treated without total parenteral nutrition (TPN).

The many protocol violations in the Glucontrol analysis that led to its premature end make it difficult to thoroughly evaluate the results’ applicability to practice. Protocol violations, however, are a logistic problem in all of the previously mentioned trials, as well as in clinical practice. Adherence to institutional insulin protocols is variable to low, with many trials reporting adherence in the 61%–72% range.19-22 Protocol violations of either correct frequency of monitoring or correct dose adjustment calculation can lead to hypoglycemic episodes or decreased time in therapeutic range. Protocol adherence of greater than 90% has been positively associated with greater time in therapeutic range.22

Hypoglycemia (less than 40 mg/dL) was significantly increased in the intensive insulin therapy arm in all five of the discussed trials (p<0.001 for all) (Figure 5.1). Of interest, the hypoglycemia that led to the early suspension of the intensive insulin therapy arm in the VISEP trial occurred less often than in the Leuven MICU study, which detected a mortality benefit in patients who were in the MICU for more than 3 days. That hypoglycemia was significantly increased in all the intensive insulin therapy arms suggests a failure of the protocols and guidelines used by the study investigators.
Further suggesting a failure of the interventions used in the primary literature is the “glycemic separation” between the different analyses (Figure 5.2). Glycemic separation is defined as the difference between the mean BG values achieved in the intensive therapy arm and those achieved in the conventional therapy arm. Investigating this shows that of the five trials discussed, only the Leuven SICU analysis was able to reach a mean BG value within the specified goal range of 80–110 mg/dL, with a glycemic separation of 50 mg/dL between interventions. Patients in the NICE-SUGAR analysis in the conventional therapy arm had a mean BG of less than 150 mg/dL, and only a 27 mg/dL glycemic separation was shown between arms.

**GUIDELINES FOR GLUCOSE MANAGEMENT IN THE ICU**
Given the controversy in the results found in the primary literature for glucose management in the ICU, multidisciplinary guidelines play an important role in guiding therapy for health professionals. Recommendations on glucose management in the critically ill population are made by several professional organizations.

**Society of Thoracic Surgeons**

The first and most specific guideline with respect to target populations is the Society of Thoracic Surgeons (STS) practice guideline for blood glucose management during adult cardiac surgery. The STS lists the following advantages to targeting BG values less than 180 mg/dL: reduced mortality, reduced morbidity, lowered incidence of wound infections, reduced hospital length of stay, and enhanced long-term survival. The STS thus recommends that cardiac surgery patients with BG values greater than 180 mg/dL receive intravenous insulin to maintain BG values below 180 mg/dL for the duration of their ICU stay (level A recommendation). The STS also recommends that patients requiring 3 or more days in the ICU have a continuous insulin infusion to keep BG values at 150 mg/dL or less (level B recommendation).

The Surgical Care Improvement Project (SCIP) as overseen by the Joint Commission made glucose management in cardiac surgery patients a reportable quality measure, citing the recommendations made in the STS guidelines. The SCIP recommendations allowed the incidence of cardiac surgery patients with a controlled postoperative BG (180 mg/dL or less) in the 18–24 hours after anesthesia to be a reportable inpatient quality measure until January 2015, when the Joint Commission announced that reporting of this measure is to be indefinitely suspended. The Joint Commission cited the requirement not reflecting current clinical guidelines as the reason for the suspension.

**ADA/AACE Consensus Statement**

In 2009, the most recent consensus statement from the American
Diabetes Association (ADA) and the American Association of Clinical Endocrinologists (AACE) on inpatient glycemic control was released.\textsuperscript{25} For the subset of critically ill patients, it is recommended to initiate insulin therapy at a BG threshold of no more than 180 mg/dL, and a goal BG value of 140–180 mg/dL is recommended for most critically ill patients. They recommend using intravenous infusions as the preferred method of delivering insulin, as well as a validated intravenous insulin protocol with demonstrated efficacy and low rates of hypoglycemia.

\textbf{Figure 5.1} Hypoglycemia in RCTs targeting 80–110 mg/dL.

MIC = medical intensive care unit; RCT = randomized controlled trial; SICU = surgical intensive care unit.
American Diabetes Association

In the 2015 recommendations for critically ill patients, the ADA recommends initiating insulin therapy at a BG concentration of no more than 180 mg/dL, with a goal BG range of 140–180 mg/dL for most critically ill patients\textsuperscript{26} (grade A recommendation). The guidelines concede, however, that tighter BG goals may be appropriate for selected patients if the intervention used to achieve them does not lead to increases in hypoglycemia (grade C recommendation). The guidelines recognize the failure of insulin protocols in RCTs, recommending that providers use an intravenous insulin protocol with demonstrated efficacy in achieving the desired glucose values without increasing the risk of severe hypoglycemia (grade E recommendation). The guidelines also strongly recommend against using sliding-scale...
insulin alone for hyperglycemia management in the hospital setting because of the reactive nature of sliding-scale insulin (grade A recommendation).

ACCM/SCCM

Further guidelines on using intravenous insulin in the critically ill population are offered from the American College of Critical Care Medicine/Society of Critical Care Medicine (ACCM/SCCM) guidelines published in 2012. These guidelines recommend initiating insulin therapy when BG values are 150 mg/dL or greater (level of evidence: low) and state that most ICU patients should be treated to a BG goal of less than 150 mg/dL and absolutely less than 180 mg/dL using a protocol that shows low rates of hypoglycemia, suggesting that BG values of 70 mg/dL or less are associated with increased mortality and that even brief BG values of 40 mg/dL or less are independently associated with a greater risk of mortality (quality of evidence: low). Blood glucose less than 100 mg/dL should be avoided during insulin infusion for brain injury patients (quality of evidence: very low).

The guidelines offer no example of an intravenous insulin protocol, though they suggest that BG be monitored routinely every 1–2 hours for most patients receiving an insulin infusion (quality of evidence: very low). Monitoring for most patients on insulin infusion can be done using most point-of-care glucose meters, even though they are not optimal, cautioning clinicians to be aware of potential limitations in accuracy for patients with anemia, hypoxia, and interfering drugs (quality of evidence: very low). Patients in shock, on vasopressor therapy, or with severe peripheral edema, and for any patient on a prolonged insulin infusion, these guidelines suggest arterial or venous whole blood sampling instead of fingerstick capillary BG testing (quality of evidence: moderate).

Surviving Sepsis Campaign

Again, different recommendations are put forth in the 2012 Surviving
Sepsis Campaign (SSC) guideline for initiation of therapy and BG target.\textsuperscript{28} The 2012 guidelines recommend initiating a protocol for glucose management when two consecutive BG concentrations are greater than 180 mg/dL in patients with severe sepsis, targeting a BG concentration of 180 mg/dL or less (grade 1A). These guidelines, like the ACCM/SCCM guidelines, offer no recommended insulin infusion protocol, though they do recommend a monitoring regimen of every 1–2 hours until glucose values and insulin infusion rates are stable, followed by every 4 hours (grade 1C). The SSC guidelines also recommend caution with BG tests obtained by point-of-care testing (POCT) (ungraded recommendation).

**American Society for Parenteral and Enteral Nutrition**

Because nutritional support is not only an important ICU issue but also a major contributor to hyperglycemia in critically ill patients, official recommendations from nutritional support and organizations have also been put forth. The American Society for Parenteral and Enteral Nutrition (ASPEN) recommends a goal BG range of 140–180 mg/dL (strong recommendation), noting no clinical trial has established outcomes for different BG targets in patients receiving nutritional support.\textsuperscript{29}

There is no clear consensus among professional organizations for the goal BG in critically ill patients, or recommendations on intravenous insulin protocols to achieve specific BG targets. The recommendations put forth in these guidelines are summarized in Table 5.2. This increases the need for vigilance at the institutional level to implement and rigorously evaluate glucose management in the ICU population using the multidisciplinary team approach.

| Table 5.2 | Summary of Recommendations of National/International Guidelines |
AREAS FOR FUTURE RESEARCH IN RCTS

Given the contradictory results of the RCTs, a more targeted approach to glucose management research in the ICU is necessary in future studies to fully understand the role of intensive insulin therapy and to best identify patients who may benefit from the intervention. In this section, we will briefly review end points that have yet to be rigorously studied prospectively.

Diagnosis of Diabetes vs. Non-diabetes

The question remains whether there should be different goal BG values for patients depending on prior to admission diabetes status. The question is based on the theory that in patients with diabetes, adaptation to a chronic hyperglycemic state may occur, and thus
patients with diabetes do not benefit from glucose values of 80–110 mg/dL because a normoglycemic range for these patients may be higher.

A retrospective cohort analysis conducted by Lanspa et al. evaluated 3,529 patients using the same protocol, allowing providers to choose between 80–110 mg/dL and 90–140 mg/dL for a goal BG concentration, in 12 ICUs across eight hospitals. After multivariate analysis, there was no significant difference in 30-day mortality between the groups with respect to glucose target. When stratified according to diabetic status, the multivariate analysis showed that the 90- to 140-mg/dL glucose target was independently associated with increased risk of mortality in patients without diabetes (p<0.05) but with decreased risk of mortality in patients with diabetes (p<0.01).

Similar to previous trials, significantly higher rates of severe hypoglycemia (less than 40 mg/dL) occurred in the cohort of patients who were treated to a goal of 80–110 mg/dL (3.6% vs. 2.0%; p<0.01). Mortality was increased in patients with at least one documented episode of severe hypoglycemia (17.3% vs. 10.3%; p<0.01). No difference in mortality was shown between goal glucose values for patients with a documented episode of severe hypoglycemia. The rate of severe hypoglycemia in this analysis was much lower than in the previously published analysis, suggesting an improvement in insulin intervention in this analysis compared with those in the RCTs described previously.

Glycemic Variability

Glycemic variability, introduced as a metric with which to monitor outpatients with type 2 diabetes mellitus, has yielded compelling results retrospectively in the critically ill population. A pooled analysis of the Leuven MICU and SICU studies examined in depth some more specific glucometrics of the patients in the RCT, including a mean daily delta BG (mean of daily [maximum-minimum] BG) as a measure of glycemic variability and a standard deviation (SD) of all glucose values that were obtained electronically.
Glycemic variability had a strong independent effect on mortality. Mean daily delta BG was significantly lower in survivors compared with non-survivors and, on multivariate analysis, was confirmed to be independently associated with mortality. The mean daily delta BG was lower in the SICU subgroup than in the MICU subgroup, raising questions regarding whether the mortality benefit in the SICU analysis may have been enhanced by the decreased glycemic variability in all patients. In the patients in the MICU subgroup, the SD of BG was lower in survivors than in non-survivors (p<0.001) and was an independent predictor of mortality using a multivariate analysis.

The ideal metric for studying glycemic variability is also a matter for debate. In addition to those discussed previously, variables assessed retrospectively across analyses include the MGL (mean glucose level), an SD of MGL, and use of a coefficient of variation (SD/MGL). It is not yet clear which, if any, of these metrics, if targeted, will lead to a decrease in mortality. Although these variables continue to provide interesting data for retrospective analysis, accurate continuous glucose monitoring will need to be used for an analysis to prospectively optimize these metrics without creating excess risk of hypoglycemia.

**Time in Target Range**

As discussed previously, the gaps showed that goal BG values and BG values achieved in clinical trials are profound. Several factors play a role in this disparity, first of which is the method by which intravenous insulin is administered and titrated, which we will discuss further in the Medications section. Frequency and method of monitoring of BG may play the largest role in detecting BG values outside the goal range. For patients on intravenous insulin, previously published analyses show variability in the recommended monitoring intervals to as often as every 30 minutes for up to 4 hours in other published data sets. If BG values are out of a specified goal range and not detected and rectified in a timely manner, the benefits of the goal glucose range may not be fully realized.

New developments in medical technology will allow for continuous
monitoring of whole BG to eliminate the need for capillary BG monitoring in the future, as well as allow real-time titration for medical providers. Continuous BG monitoring could also decrease the occurrence of severe hypoglycemia. Challenges in implementing continuous BG monitoring will include the cost to institutions, both in equipment and in staff training. Although proprietary continuous BG monitoring systems have shown success in reaching BG values of 80–110 mg/dL with very small rates of severe hypoglycemia, these systems should next be evaluated in a randomized fashion against a conventional glucose management protocol cohort to evaluate for differences in morbidity and mortality as well as the development of hypoglycemia.

**Monitoring in Critically Ill Patients**

Because specific BG values are so closely linked with the treatment selected, it is important for members of the multidisciplinary team to understand the methods available for BG monitoring and the advantages and disadvantages of each method.

**Frequency of BG Monitoring in the ICU**

There is no primary literature showing the optimal BG monitoring regimen for patients in the ICU. Most ICU patients should have BG checks at least every 6 hours to screen for hyperglycemia. Patients in the ICU on intravenous insulin should have BG testing hourly on initiation and whenever a rate change to the infusion takes place. More frequent BG testing should occur on any changes in their source of glucose such as held tube feeds. If aggressive monitoring is not done in patients on insulin infusions, episodes of hypoglycemia and hyperglycemia may be missed. Only when insulin rates are stable for several hours should less BG monitoring occur. Patients who can be treated subcutaneously and eat discrete meals can be tested preprandially and at bedtime.
Methods of Monitoring BG in the ICU

The most common methods for BG monitoring are bedside or POCT devices and laboratory determination using a sample obtained by venipuncture. Point-of-care testing devices usually use capillary blood obtained by fingerstick. Although the results are available within minutes, use of these devices requires training of nursing staff to ensure proper technique for adequate results. The convenience of use and fast result times with POCT devices remain their major benefits of use. Unfortunately, accuracy with using POCT devices is decreased compared with methods used in a central laboratory.\(^{36}\) There is demonstrated variability between glucose meters as well as test strips that can vary from lot to lot. This is a fundamental issue with POCT BG monitoring systems because the U.S. Food and Drug Administration (FDA) requirement for accuracy is that displayed values be within 20% of the actual BG for all readings greater than 75 mg/dL.\(^{37}\)

Point-of-care testing devices can measure blood samples from arterial, venous, or capillary blood, depending on the patient’s available access points for nursing staff. Because reasonable variability is expected between each of these sites, patients should be consistently assessed at the same site. Comparing POCT results from different sites concurrently could lead to erroneous intervention, potentially leading to hypoglycemia or hyperglycemia.

Samples collected by venipuncture and sent to a central laboratory are usually processed with a whole blood analyzer or an arterial blood gas analyzer. These methods produce the most accurate results; however, using them takes considerably more time to collect the results, which may not be appropriate for the frequency of BG monitoring required for critically ill patients.\(^{38}\)

To summarize, the risks and benefits of POCT compared with laboratory BG testing include many pros and cons. Starting with a cost consideration, using capillary whole blood is the least expensive method; however, it allows for the largest possibility of inaccurate results. Using an arterial catheter increases the cost and requires catheter changes every several days, depending on institutional standards. In an attempt to decrease the variability of BG readings
from POCT devices, a formal internal training program should be implemented for use with all POCT devices for BG. This policy should dictate the use of only a single brand and model of POCT devices and the routine use of quality control solutions on all devices.

Controversies with POCT in Critically Ill Patients

The convenience of POCT for BG in the critically ill population has made it a standard of care in many ICUs. However, there is controversy about the appropriateness of this practice. In January 2014, an FDA memorandum stated that there was not yet a POCT device with labeled use in the critically ill population, and a guidance was released for what the FDA would request to label devices for use in the critically ill population. This included an evaluation of meter precision so that 99% of all values achieved are within 10% of the reference method for BG values greater than 70 mg/dL. In April 2014, the American Association for Clinical Chemistry provided a rebuttal to the requirements put forth by the FDA, suggesting that they unnecessarily increase the regulatory burden and health care system costs without a demonstrable benefit in patient care.

In September 2014, the FDA approved the Nova Stat-Strip glucose hospital meter system for use in critically ill patients, making it the first POCT device for BG monitoring approved by the FDA. Of note, the device is only meant to be used with arterial and venous blood samples, so the convenience of POCT devices using capillary blood samples is still an obstacle to overcome. It is anticipated that in the coming years, the Joint Commission, the accrediting body for Centers for Medicare & Medicaid Services reimbursement, will begin issuing citations to institutions using unapproved POCT for BG measurement in critically ill patients.

In March 2015, the FDA temporarily withdrew its initial memorandum and reissued it in draft form only. The FDA stated that although off-label use of meters is not prohibited, additional safeguards should be in place when this practice is used. The FDA is currently obtaining more information on using POCT glucose monitoring systems from
manufacturers and hospitals, as well as trying to promote education regarding requirements put forth under the Clinical Laboratory Improvement Amendments. This controversy has not yet been resolved and will continue to unfold and shape clinical practice for the next several years.

MEDICATIONS

In this section, we will discuss available medications and review their role in the treatment of the critically ill population.

Oral Antidiabetic Medications

Oral antidiabetic medications are generally not preferred in the acute setting for critically ill patients who may be experiencing decreased absorption from their gastrointestinal tract. Many oral antidiabetic medications rely on hepatic or renal metabolism or excretion. Because end-organ function may be fluctuating or impaired in critical illness, clearance of oral agents may be impaired. This can lead to increased adverse effects such as hypoglycemia with sulfonylureas or lactic acidosis with metformin. The 2009 ADA consensus statement states that noninsulin agents are inappropriate in most hospitalized patients.\textsuperscript{25}

Insulin

Insulin therapy is usually the treatment of choice when managing hyperglycemia in the critically ill population. Insulin is versatile, considering the many available formulations and their ability to be administered by several routes. When deciding whether to treat a patient by the intravenous or subcutaneous route, many factors should be considered. In the acute phases of critical illness, patients may require vasopressor support and have rapidly changing insulin requirements, generalized edema, impaired subcutaneous perfusion, and/or variable nutritional support, all of which make the subcutaneous route non-ideal for administering insulin in the critically ill patient.
Intravenous insulin infusions provide advantages over the subcutaneous route in critically ill patients with respect to rapidity of onset of effect and overall ability to achieve glycemic targets. With intravenous insulin, hypoglycemia occurs for shorter periods, whereas in the same patient receiving repeated subcutaneous doses of insulin, it may result in a “stacking” of the insulin’s effect, causing protracted hypoglycemia, given that the pharmacologic effect of subcutaneous insulin is longer than that of intravenous insulin.

### Intravenous Infusions

As discussed in the previous section on guidelines for glucose management in the ICU, intravenous infusions often require the use of an intravenous insulin protocol with demonstrated efficacy and safety in achieving desired glucose goals without increasing the risk of severe hypoglycemia. A standardized trigger point should be set for initiating intravenous insulin in the critically ill patient. We recommend initiating an insulin infusion in ICU patients with at least one of the following:
Critically ill with a BG greater than 180 mg/dL and an expected ICU stay greater than 3 days

All with type 1 diabetes mellitus

With an unstable clinical condition (e.g., steroids, pressors, variable nutrition) and at a high risk of hyperglycemia

With BG persistently elevated and not controlled with subcutaneous insulin therapy

Intravenous insulin protocols may be initiated with or without a bolus dose. If electing to use a bolus dose, the bolus and initial rate of insulin should be based on the patient’s BG concentration (Table 5.3). If not using a bolus dose, the initial rate of insulin should still be based on the patient’s initial BG concentration (Table 5.4).

After initiating an insulin infusion, providers have options. We will compare two commonly used types of intravenous insulin titration protocols: the “fixed” insulin titration protocol and protocols that use an adjustment factor.

**Fixed Protocol**

A fixed insulin titration protocol refers to a protocol that recommends a change to the infusion rate only according to the current glucose concentration. An example of a fixed insulin titration protocol can be found in Table 5.5.

The primary advantage of a fixed-dose titration is ease of use by the end user. Titrations of 1 unit/hour are unlikely to lead to errors in the administered amount. A primary disadvantage of using the fixed titration protocols is the lack of accounting for the rate of change in the patient’s BG. For example, a patient with a BG value of 130 mg/dL would continue on the same rate of insulin currently being administered, regardless of whether the previous hour’s BG value was 140 mg/dL or 300 mg/dL. For a patient who is changing more than 100 mg/dL over 1 hour, there is an increased likelihood that the BG value will continue to fall, placing the patient at a higher risk of hypoglycemia on the next BG check. These changes in glucose may not always be so dramatic
because a downward trend in BG values could be seen for hours and not recognized until hypoglycemia occurs. Fixed intravenous insulin protocols typically do not differentiate between patients’ variable levels of insulin sensitivity or resistance, which causes delays in achieving goal BG concentrations.

**Adjustment Factor Protocols**

Intravenous insulin titration protocols that account for the rate of change between hourly BG values are called adjustment factor protocols. An example of an adjustment factor protocol can be seen in Table 5.6. On receipt of the current BG value, the bedside practitioner can examine the relationship with the previous hour’s BG and the rate of change between the two. The bedside practitioner then multiplies the infusion rate according to the protocol.

Continuous titrations with an adjustment factor protocol require frequent calculations by bedside providers. This introduces a potential source for errors to be made in calculation, decreasing compliance with the protocol. To aid in calculation, institutions can have the continuous calculation done using a paper chart or electronic software. Paper-based protocols may be more labor-intensive to bedside providers, though an evaluation of the example protocol provided earlier as a paper-based insulin titration was effective at achieving an average BG of 145 mg/dL with minimal hypoglycemic events.

Software-based protocols provide an advantage to paper-based protocols in many ways. First, an electronic titration protocol removes the potential for human error with calculations on rate adjustments. An electronic protocol also provides the ICU team with an avenue to potentially change the glucose targets for a specific patient and to calculate infusion rates using a rate of change to try to achieve a different glycemic target. Electronic protocols can account for insulin sensitivity across different patients and recommend more aggressive rate changes in resistant patients and less aggressive adjustments in sensitive patients, such as patients with type 1 diabetes mellitus. Electronic protocols also provide prompts for continued glucose
monitoring at intervals that can be specified by the protocol, rather than have changes initiated by the bedside provider, as is done with the paper-based protocol.

Subcutaneous Basal/Bolus

Given the high-risk nature of insulin and the many available products, it is imperative that the ICU pharmacist be familiar with the different profiles of available insulin products. Table 5.7 summarizes these profiles.

When initiating a subcutaneous regimen, it is recommended to initiate a weight-based dosing regimen (0.3–0.5 unit/kg). The weight-based amount should be distributed to be administered to the patient throughout the day. Usual recommendations are for basal insulin to be 40%–50% of the total daily dose (TDD) and for nutritional insulin to be 50%–60%. When choosing to manage hyperglycemia in the critically ill patient by the subcutaneous route, it is important that each patient’s regimen consist of three insulin types: basal, nutritional/prandial, and correctional.35,46-48

Basal

Basal insulin refers to the patient’s insulin requirements that exist regardless of the patient’s caloric intake. Basal insulin should be given to patients regardless of whether they are eating or not eating. Options for basal insulin can be either a once-daily dose of a long-acting insulin such as insulin glargine or insulin detemir or a twice-daily intermediate-acting insulin such as neutral protamine Hagedorn (NPH).

Nutritional

Critically ill patient situations are often unstable, and patients’ caloric
intake can fluctuate for several reasons such as nothing by mouth (NPO) for procedure, loss of naso-gastric tube access, and emesis. For these reasons, it is important to separate out nutritional insulin administration from the previously mentioned basal insulin administration. It is also important that orders be written correctly to allow for acute changes in carbohydrate intake; in such instances, prandial insulin doses can be held to avoid causing episodes of hypoglycemia.

When choosing a nutritional or prandial insulin product, it is of utmost importance to distinguish the source of a patient’s glucose intake. For patients who are on a continuous hourly rate of tube feeding or receiving TPN, providing a fixed dose of regular insulin every 6 hours should provide consistent coverage and avoid the stacking of insulin doses. For patients eating discrete meals or receiving bolus tube feeding, using rapid-acting insulin such as insulin aspart or insulin lispro before meals to cover the carbohydrate intake is preferred because the insulin analogs offer a profile similar to the natural pancreatic insulin production in response to carbohydrate intake.

</tbody>
</table>

The above protocol can be used as a guide for the ICU team to account for the rate of change of BG between hourly BG checks. With each new BG result available, the prescriber, nurse, or ICU pharmacist can examine the relationship with the previous hour’s BG and the rate of change between the two. This chart will titrate to a mean BG of 145 mg/dL. The chart will then instruct the ICU team on how to adjust the insulin infusion rate according to a multiplication factor. Because calculations are often made for patients treated according to a protocol like this one, it is important to have safety checks in place to ensure the calculations are done accurately, either electronic or human double-check.
Correctionsal Insulin

The final piece to a successful subcutaneous insulin regimen is correctional insulin, to be administered on top of, and at the same time as, the patient’s prandial insulin. Correctional insulin is usually seen in the form of sliding-scale insulin. There should be different levels of sliding-scale insulin, designed for the patient’s level of insulin sensitivity, which can be determined by counting the patient’s daily requirement of insulin units. An example of sliding-scale insulin delivered according to scheduled insulin requirement can be found in Table 5.8.

An important point in managing hyperglycemia is to avoid monotherapy with sliding-scale insulin. The monitoring provided with a sliding scale is important information; however, managing hyperglycemia with only a sliding scale is reactive, rather than proactive, in avoiding hyperglycemia.

Transition from Intravenous to Subcutaneous

For patients initially treated with an intravenous insulin infusion, transition to a subcutaneous regimen should be considered when one of the following criteria is met:

- The patient is ready for transfer from the ICU

</tbody>
</table>
The patient has been on a stable dose of the insulin drip for more than 24 hours; the glucose is controlled, and the patient is no longer critically ill.

To transition patients from intravenous to subcutaneous insulin safely, the critical care pharmacist should:

1. Determine the TDD of insulin according to the insulin infusion rate for past 6 hours.
2. TDD = (average insulin drip rate for past 6 hours) × 24 hours
3. Reduce the TDD to around 80% of the above; because insulin is a protein, about 20% of the hourly rate of intravenous insulin will bind to intravenous bags or intravenous tubing and, as such, will not reach the patient.\(^{49}\)
4. Give 50% of the TDD as basal insulin and 50% as nutritional insulin. If the patient is NPO, give 100% of TDD as basal insulin.
5. Give supplemental insulin sliding scale according to the TDD.
6. Stop the insulin drip 1–2 hours after the first dose of prandial insulin or 2–3 hours after the first dose of basal insulin is administered.

Example Patient Cases

1. Conversion from intravenous to subcutaneous insulin in a patient receiving nutrition. If the average insulin infusion rate for the past 6 hours is 2.5 units/hour:
   - TDD is 2.5 units/hour × 24 hours = 60 units
   - 80% of 60 units = 48 units
   - Basal insulin = 24 units/day
     - Insulin NPH 12 units every morning and 12 units every evening

OR
• Insulin glargine 24 units every morning or every evening
  ▪ Nutritional insulin = 24 units/day
  • If the patient is eating discrete meals: 8 units of insulin aspart three times daily with meals
  • If the patient is on continuous tube feeds or TPN: 6 units of regular insulin every 6 hours

• Correctional insulin
  • Discrete meals: insulin aspart with meals
  • Continuous tube feeds, TPN: regular insulin every 6 hours

2. Conversion from intravenous to subcutaneous insulin in a patient NOT receiving nutrition (NPO). If the average insulin rate for the past 6 hours is 2.5 units/hour:
  ▪ TDD is 2.5 units/hour × 24 hours = 60 units
  ▪ 80% of 60 units = 48 units
  ▪ Basal insulin = 48 units/day
    • Insulin NPH 24 units every morning and 24 units every evening
  OR
  • Insulin glargine 48 units every morning or every evening
    ▪ Nutritional insulin = none
    ▪ Correctional insulin
      • NPO: regular insulin every 6 hours

| Table 5.8 | Example of Correctional Insulin Scales Based on Scheduled Insulin Requirement |
Medication Reconciliation

Many patients with a diagnosis of diabetes before their hospitalization will be on existing pharmacotherapy for managing the disease. It is often suggested to continue patients on their outpatient regimen on admission to the ICU. It is important to recognize that critically ill patients are often unstable, and as such, continuing a patient’s home regimen may not be appropriate when patients are in the ICU. Patients’ home regimens may incorporate oral agents that may cause toxicities when organ function is compromised, or consist of products that are not carried on an institution’s formulary such as combination insulin products. Sources of carbohydrate intake are also likely to be variable in the ICU compared with the patient’s pre-hospital glucose intake.

Considering all of the previously mentioned variables, no single algorithm is suitable for use in all ICU patients. Some patients may benefit most from an intravenous insulin infusion, whereas others may benefit most from a subcutaneous regimen. Monitoring BG values closely when the patient in the ICU is of paramount importance, and when reassessing medications on discharge from the ICU to non-ICU floors, it may be appropriate to reinitiate elements of a patient’s home antidiabetic regimen.

Management of Hypoglycemia

When patients have hypoglycemia, swift intervention is required to minimize the potential for lasting adverse events. Signs and symptoms of hypoglycemia include confusion, diaphoresis, irritability, slurred
speech, fatigue, disorientation, and, in severe cases, loss of consciousness, seizures, and decreased response to noxious stimuli. When hypoglycemia is suspected, a POCT glucose measurement should be obtained as quickly as possible. If patients are determined to be hypoglycemic with a symptomatic BG of 70 mg/dL or less, they will require treatment. If the patient is NPO or unresponsive and intravenous access is available, 12.5–25 g of dextrose 50% should be administered. If the patient is NPO or unresponsive and intravenous access is not available, 1 mg of glucagon intramuscularly should be administered. If a patient is responsive and able to receive enteral glucose, institutions should have a protocol in place to guide practitioners in administering 15–20 g of oral carbohydrate. Examples of rapid-acting carbohydrates are 4 oz of fruit juice or a non-diet soda, or 3 to 4 glucose tablets. After supplementation, the patient’s BG values should be reassessed every 15 minutes until the BG is greater than 70 mg/dL. Providers should be cautious of overcorrecting with treatment of hypoglycemia, which could potentially lead to hyperglycemia. One retrospective analysis of critically ill patients who received dextrose 50% while on an insulin infusion showed that the median increase in BG was 4 mg/dL per gram of dextrose 50% administered.

After stabilizing the hypoglycemic episode, the ICU team should try to identify the cause of the episode. Once the cause has been identified, modifications should be made to the patient’s current management regimen, including glucose source and insulin regimen.

**HYPERGLYCEMIC EMERGENCY MANAGEMENT**

The most serious acute complications of hyperglycemia are DKA and HHS. Diabetic ketoacidosis most often clinically manifests with uncontrolled hyperglycemia, metabolic acidosis, and an increase in ketone production. Patients with HHS often present with dehydration, hyperglycemia, and hyperosmolality, usually in the absence of a significant acidosis. Most patients presenting with DKA have type 1 diabetes mellitus; however, patients having type 2 diabetes mellitus...
with a precipitating illness such as infection are also at risk of progressing to DKA.

**Pathophysiology**

Diabetic ketoacidosis and HHS are caused by a complex metabolic process that results from the combination of absolute or relative insulin deficiency. Episodes of DKA and HHS usually develop secondary to an underlying cause. The most common cause of DKA and HHS is infection. Other common causes are inadequate insulin therapy (including patient nonadherence), pancreatitis, myocardial infarction, and medications. Severe dehydration that progresses to HHS can occur in chronic illnesses with decreased water intake, potentially because patients are bedridden. Many patients who develop HHS have no previous diagnosis of diabetes, so the development of HHS is not recognized in a timely manner, and treatment is not initiated early.

Many medications have been implicated as precipitating factors for hyperglycemic emergencies, including corticosteroids, thiazide diuretics, and atypical antipsychotic agents. The initiating factor can cause hyperglycemia because of increased gluconeogenesis and decreased glucose use by peripheral tissues. The hyperglycemic process can progress to DKA or HHS because of a combination of absolute or relative insulin deficiency and an increase in counterregulatory hormones such as glucagon. The resulting insulin deficiency and increased hormone productions will also lead to lipolysis from adipose tissue and increased hepatic ketone production, ultimately causing a metabolic acidosis.

**Management**

The most recent consensus statement from the ADA on the management of DKA and HHS was published in 2009. The ADA put forth treatment strategies, including monitoring, correction of fluid and electrolyte status, and insulin therapy for patients with DKA and HHS. We will discuss these treatment strategies in this section.
Laboratory Values/Diagnosis

Classifying the severity of episodes of DKA and HHS can be important when determining optimal treatment strategies as well as when determining the level of care patients will require on admission to the hospital. Table 5.9 describes the classification of severity of episodes of DKA and HHS. Severity of DKA is classified into mild, moderate, and severe DKA according to laboratory findings. Some patients may present with a mixed picture of both DKA and HHS.

Although DKA is not a diagnosis of exclusion, several other disease states can produce some of the same laboratory abnormalities. Alternative causes of ketoacidosis include starvation ketosis and alcoholic ketoacidosis; however, these cases often also present with uncontrolled hyperglycemia. A severe anion gap metabolic acidosis can present from several toxic ingestions such as ethylene glycol, salicylates, and methanol. For these reasons, it is important to do a thorough history, including previous drug use, to ensure an adequate diagnosis.

Fluids

Initially, the goal of fluid therapy should be to expand the patient’s intravascular and interstitial volume because both are reduced in a patient with a hyperglycemic emergency. The resuscitation fluid of choice in a hyperglycemic emergency is 0.9% sodium chloride, initially infused at a rate of 15–20 mL/kg/hour, or as 1–1.5 L during the first hour. Patient-specific adjustments should be considered in patients with known cardiac or renal dysfunction to avoid causing dramatic fluid overload. After the initial bolus, the maintenance fluid rate should be based on physiologic parameters to maintain hemodynamic stability as well as the intravascular and extravascular volume. Providers should also calculate a corrected sodium (corrected sodium = measured sodium + 0.016 × [serum glucose 100 mg/dL]). If the corrected sodium is high or normal, use of 0.45% sodium chloride at a rate of 250–500 mL/hour is appropriate. If the corrected sodium is low, maintenance fluid resuscitation should continue with 0.9% sodium chloride.
Hyperglycemia will likely resolve before the ketoacidosis has resolved; as such, providers should consider adding dextrose 5% in water in patients with DKA having a BG less than 200 mg/dL or an anion gap less than 12 and in patients with HHS having a BG less than 300 mg/dL or until osmolality is less than 315 mOsm/kg and until patients are mentally alert or receiving carbohydrates in the form of nutrition. Monitoring of serum chloride is also important because large volumes of sodium chloride-containing resuscitation fluids are often given to patients undergoing a DKA/HHS episode. Excessive chloride administration can lead to a prematurely closed anion gap, complicating assessment of the patient’s acid-base status. In these patients, it may be appropriate to change to a non–chloride-containing resuscitation fluid.

### Electrolytes

In addition to monitoring sodium concentrations when determining the fluid and rate of resuscitation, other electrolyte abnormalities that need to be managed in patients having a hyperglycemic emergency include potassium, bicarbonate, and phosphate.

Potassium management in a patient with DKA/HHS can prove the most complicated. Many patients have a mild-moderate hyperkalemia on presentation. On initiation of fluid resuscitation, insulin therapy, and
correction of the ketoacidosis, a shift toward decreased serum potassium concentration occurs. To prevent the occurrence of severe hypokalemia, it is recommended to initiate potassium supplementation when serum potassium concentrations fall below 5 mEq/L. This can be achieved using a potassium chloride–containing maintenance fluid. If severe hypokalemia occurs, patients may require placement of a central venous catheter to allow infusion of concentrated potassium chloride. If patients require greater than 10 mEq of potassium chloride per hour, cardiac monitoring should be initiated. In the rare case that patients having a hyperglycemic emergency are severely hypokalemic (potassium value less than 3.3 mEq/L) on presentation, insulin therapy should be delayed until a potassium value greater than 3.3 mEq is obtained.

Using sodium bicarbonate in DKA is controversial; current recommendations favor adding intravenous sodium bicarbonate only in patients with a severe acidosis (pH less than 6.9) who are hypotensive and not responsive to intravenous fluids.

Similar to potassium, serum phosphate concentrations also decrease after initiating insulin therapy. Currently, no benefit on clinical outcomes has been shown with phosphate supplementation of patients in DKA. Because of concern for excess phosphate supplementation causing hypocalcemia, routine phosphate supplementation is not recommended for patients with a phosphate concentration greater than 1.0 mmol/dL.

Insulin

Intravenous insulin therapy is the mainstay of therapy in patients with DKA and HHS in the ICU, though patients with an uncomplicated mild-moderate episode of DKA and HHS can be treated safely and effectively by a subcutaneous regimen. Patient-specific factors such as hemodynamic status and etiology of DKA/HHS should be considered when selecting the route of administration for insulin because severely ill patients may have decreased subcutaneous absorption.

An example of a weight-based intravenous insulin regimen is described in Table 5.10. Currently, debate exists about whether to
initiate therapy using an intravenous bolus of insulin. If using an intravenous insulin bolus, the dose recommended is 0.1 unit/kg of actual body weight, and the initial rate of insulin should be 0.1 unit/kg/hour. If therapy is not initiated using an insulin bolus, it is recommended to initiate therapy at 0.14 unit/kg/hour. Hourly monitoring of BG is recommended, and strategies for adjusting the rate of insulin infusion can be found in Table 5.10.

The transition from intravenous insulin to subcutaneous insulin should take place once the DKA/HHS episode has resolved. Resolution of DKA is described as a BG less than 200 mg/dL and two of the following: serum bicarbonate greater than 15 mEq/L, venous pH greater than 7.3, and anion gap less than 12. Resolution of HHS is described as a BG less than 300 mg/dL, a plasma osmolality less than 315 mOsm/kg, and a patient who is mentally alert. It is critical to overlap the first dose of subcutaneous insulin with the infusion by 1–2 hours before discontinuing the infusion. Patients who were on a stable regimen of insulin before the DKA/HHS episode may be reinitiated on their previous regimen if the underlying cause of the emergency has been resolved. Patients who are insulin naive can be initiated on a weight-based subcutaneous regimen of 0.5–0.8 unit per day, split between a basal insulin and a nutritional insulin. A correctional component (sliding scale) of BG monitoring several times daily is also critical for a complete subcutaneous regimen.

</tr>
</tbody>
</table>
If BG decreases > 75 mg/dL per hour

Decrease infusion rate to 0.05 unit/kg/hr

DKA: If BG is < 250 mg/dL

0.05 unit/kg/hr until anion gap is < 12

HHS: if BG is < 300 mg/dL

0.05 unit/kg/hr until osmolality is < 315 mOsm/kg

For patients determined to be appropriate candidates for subcutaneously administered insulin, recommendations for dosing can be found in Table 5.11. A similar rate of ketone reduction should be expected between patients who are treated with intravenous or subcutaneous insulin; however, until further research is available, subcutaneous insulin may not be ideal for patients with severe DKA, anasarca, or hemodynamic instability.

Follow-up and Diabetes Education

Although it may not be required while patients are in the ICU, consultation with an available local clinical management team such as endocrine or a diabetes management service should be considered for patients with complicated DKA/HHS or for patients with a new diagnosis of diabetes to provide a continuity of care when the patients go to the general ward and are eventually discharged. Diabetes education to enforce medication adherence, as well as to show how to recognize the signs and symptoms of hypoglycemia and hyperglycemia, may also be appropriate for patients who may be able to avoid progression to DKA/HHS in the future. Follow-up with existing or new diabetes outpatient providers should be ensured before discharge to prevent readmission.

TEAM APPROACH

Because insulin is a high-risk medication and the primary medication for inpatient management of hyperglycemia, implementing a safe and effective environment for glucose management in the ICU requires resources across several disciplines. When implementing treatment
protocols to optimize patient care outcomes and minimize adverse events, a standardized, multidisciplinary team approach should be used.

In this section, we will describe two main types of glucose teams: (1) the “multidisciplinary steering committee” with a focus on global oversight of glucose management for an institution and (2) the best practice “clinical management team” with a focus on bedside clinical management of a patient’s glucose.55

</tr>
</tbody>
</table>

**Multidisciplinary Steering Committee**

The multidisciplinary steering committee’s role is to provide global oversight of its institution’s development and implementation of policies, order sets, protocols, and guidelines. The goals of the multidisciplinary committee should be individualized to the needs of the institution; these goals should be established and agreed on at the time of formation and maintained through future works. The multidisciplinary steering committee should focus on protocol development, implementation, and performance improvement. When forming committee goals, optimizing patient outcomes put forth by nationally established performance metrics should be primary points of interest for quality improvement projects and new initiatives.

Implementing a new guideline or protocol, or changing the current
culture, should address a few key principles. A new directive or initiative should help simplify providers' ability to treat their patients while being highly reliable to ensure long-term compliance. Current workflow and patient care demands should be considered before implementing change because it will potentially have both a positive and a negative impact on current daily practice.

Metrics that can be assessed by the multidisciplinary committee include, but are not limited to, instances of BG less than 70 mg/dL stratified per patient-days, recurrent hypoglycemia, and percentage of BG readings per stay in the therapeutic range. The committee can also conduct medication use evaluations to evaluate hypoglycemia evaluation and treatment, intravenous-to-subcutaneous transitions, and efficacy and safety of insulin infusions.

Once a steering committee or task force team has been formed and subsequent committees and task forces have been identified, key stakeholders need to be informed of the intentions of this team. This is to ensure early adoption of the steering committee’s or task force team’s goals and directives and help plan educational efforts. Stakeholders to consider are physicians from different patient care areas, particularly medical directors, the chief medical officer, the pharmacy and therapeutics committee, departmental committees, nursing leadership, nutrition services, and information and technology services, as well as all other parties involved in direct patient care. Sustained feedback from stakeholders is necessary to revise the goals and directives continually to ensure that the most current needs of the institution are being met.

Designated champions from each involved discipline may be necessary to implement the initiatives put forth by the multidisciplinary team on a departmental basis. Disciplines that should be involved in glucose management teams include pharmacists, physicians, nurses, data analysts, and nutritionists, among others. Because members of the steering committee often serve as liaisons to other institutional bodies, designated representatives of each discipline must be familiar with the principles of managing hyperglycemia and hypoglycemia in the critically ill population.
Once an area for improvement has been identified, the committee determines the best course of action for implementing change according to the expertise of its members and institutional support with resources. Guidelines and protocols are essential because they improve outcomes in BG management. A new policy, order set, protocol, or guideline may not always be the best option if existing guidance exists at the institution; however, existing protocols often need to be revised as more information becomes available from internal analyses. The goal of a committee should be to provide encompassing direction without overburdening staff with excess policies and guidelines.

The steering committee should anticipate and plan for barriers to successful implementation and have a system in place to monitor for success or opportunities for improvement once the change has been implemented.

For critically ill patients, the focus should be placed on identifying the causes of hypoglycemia and developing protocols for intravenous insulin infusions and transitioning patients from infusions to subcutaneous insulin regimens during the transition to general wards. Administering intravenous insulin requires trained nurses with explicit instructions for use. Because of the increased workload on ICU nurses administering intravenous insulin, it is critical to address nursing concerns when implementing changes as well as to have extensive educational sessions surrounding implementation. A key part of this education should be focused on how the proposed change works and the impact the change will have on nurses’ daily lives. Describing the rationale to bedside staff will create allies for future changes and will often increase awareness of why changes are needed once the efforts have begun. Example guidelines for intravenous insulin protocols and converting a patient from an intravenous insulin infusion to a subcutaneous regimen can be found in the Medications section of this chapter.

Other specialized guidelines or protocols pertinent to patient care include those regarding DKA or HHS. Creating and adhering to these protocols improve clinical outcomes without increasing the incidence of
adverse events such as hypoglycemia.57

Clinical Management Team

In addition to the steering committee, some health care systems may have a “clinical management team” doing consultative services for individual patients. The order sets, protocols, and guidelines developed by the steering committee should assist multidisciplinary providers in treating most patients. Complex patient cases in the acute care setting may require assistance beyond what is offered by these guidelines, and in these cases, the clinical management team serves to offer expert guidance. Clinical management teams can include endocrinologists, endocrine fellows, hospitalists, nurse practitioners, physician assistants, and clinical pharmacists. In addition to bedside practice, the clinical management team can be involved in staff education, discharge planning and counseling, and facilitating change in culture.

One example of a clinical management service consisted of a nurse practitioner, physician assistant, endocrine fellow, and attending endocrinologist who provided consults to surgical patients.56 The team used hospital glucose treatment protocols, with a clinically acceptable BG range of 80–180 mg/dL, to treat patients as they transitioned from intravenous to subcutaneous insulin therapy while minimizing significant hypoglycemia (less than 60 mg/dL) and hyperglycemia (greater than 400 mg/dL). The management service achieved clinically acceptable BG concentrations in 74.3% of the glycemic values with low rates of hypoglycemia and hyperglycemia, which was accepted by the surgical staff. An observational analysis of a clinical management team using a designated group of pharmacists yielded similar results. The team worked on a consultation basis using a protocol to manage perioperative dysglycemia during hospitalization with goal point-of-care BG values of 70–180 mg/dL.58 The main aims of the protocol used in this analysis targeted appropriate use of intravenous and subcutaneous insulin, including titration and how to transition to a subcutaneous regimen. A total of 1,294 patients in the preintervention group were
compared with 4,842 patients in the postintervention. The analysis showed a 12.9% increase in patient-days with goal glycemic control (90.3% vs. 77.4%) with a decrease in hypoglycemia, defined as a point-of-care BG less than 70 mg/dL, of 4% (4.6% vs. 8.6%). Using this protocol and the glycemic control team improved both the efficacy and the safety of glucose management in a perioperative patient population.

In addition to improved patient care, the clinical management service model may generate revenue if advanced practice clinicians are able to bill for consultation services. An unfortunate potential cultural shift to instituting a clinical management team for glucose management is the perception that interns and residents may be less engaged in managing glucose therapy and may start to refer un-complicated patients to the clinical management team.

Glucose management in the inpatient setting requires a multidisciplinary team approach. Creating a steering committee or task force focused on development, oversight, implementation, and quality assessment and improvement can standardize and coordinate glucose management measures within an institution. Clinical glucose management teams with a focus on direct patient care may also help improve patient outcomes.

CONCLUSION

Glucose management is an important issue in the treatment of all critically patients. Episodes of hypoglycemia and hyperglycemia alike can increase morbidity, length of stay, and mortality. Many aspects of glucose management in the critically ill population remain controversial, including monitoring, treatment goals, and the ideal intravenous insulin protocol. These challenges have led to glucose management as a popular area for research as well as a quality measure for accrediting bodies. Because of the high-risk nature of the medications involved in glucose management, the ICU pharmacist can play a significant role in ensuring the safe and effective management of their patients’ BG values.

LEARNING OBJECTIVES

1. Describe the incidence of pain, consequences of inadequate treatment, and unique challenges pertinent to analgesia in the critically ill.

2. Design a plan for the assessment of pain in communicative and noncommunicative patients.

3. Construct an analgosedation approach for the management of patient comfort.

4. Compare and contrast commonly used opioids in the intensive care unit (ICU).

5. Explain the role of non-opioids as part of a multimodal plan for the management of pain.

6. Describe evidence to support nonpharmacologic therapy for the provision of analgesia.

7. Discuss the evidence to support the use of ketamine in the critically ill.

8. Develop a strategy to optimize pain management during procedures.

9. Explain concepts pertaining to opioid conversions in the ICU.

10. Design an approach to optimize pain control during transition from the ICU to the general ward.

INTRODUCTION

Most patients who are admitted to the intensive care unit (ICU) will experience pain, and the optimal management of pain is humane, necessary, and a basic human right.¹,² The definition of pain according to the International Association for the Study of Pain is an “unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.”³ This definition is not unique to the critically ill population, but it highlights the fact that pain is subjective, and the best assessment is one that is self-reported. Thus, good communication between patients and providers is crucial for optimizing patient comfort. However, self-reported pain in the ICU is only possible in a subset of patients who can communicate, either verbally or nonverbally. But the absence of self-report, which is the norm in most critically ill patients, should not be construed as a lack of pain. Thus, additional precautions need to be taken in these patients.⁴
Critically ill patients usually have several sources of pain, including injury, surgery, acute illness, and comorbidities. Some patients may have chronic pain conditions before ICU admission, amplifying the pain experienced during critical illness. In addition, diagnostic and therapeutic procedures commonly done in the critically ill population such as turning, endotracheal suction, wound dressing changes and drain removal, incision and drainage, chest tube placement and removal, and central line placement, among others, are a great source of pain and discomfort. Prolonged mechanical ventilation itself can be a very bothersome and stressful experience for patients. The inadequate management of pain can have long-term physiological and psychological consequences. Stressors such as pain in the ICU have been associated with negative effects on health-related quality of life and posttraumatic stress syndrome. This occurs to a greater extent as the severity of illness increases.

In this chapter, the appropriate assessment of pain in communicative and noncommunicative patients is discussed because this serves as the foundation for optimizing drug therapy use for the treatment of pain. Analgesia and sedation are interrelated, and both need to be optimized for patient comfort. This chapter focuses on analgesics and their role in the provision of analgesia-based sedation. Therapeutic options are discussed, including the commonly used opioids, and non-opioids, for somatic and neuropathic pain. The role of nonpharmacologic therapy is also briefly examined. Finally, special situations that commonly occur in the ICU such as pain management during procedures, concepts pertaining to opioid conversions, and optimizing the transition from the ICU to the general ward are reviewed to provide a comprehensive understanding of all aspects of analgesia in the ICU.

PAIN ASSESSMENT

Adequate pain assessment that incorporates the unique characteristics of the critically ill population serves as a foundation for optimal pain management. The systematic evaluation of pain and agitation, together with an effective management plan, not only decreases the incidence of
pain and agitation, but also results in a decreased duration of mechanical ventilation, lower incidence of nosocomial infections, and shorter ICU length of stay.\textsuperscript{10,11} This was shown in a two-phase prospective study in which a systematic evaluation plan was implemented that included a routine assessment of pain at rest, during and after any procedures, and several other times during the day by bedside nurses.\textsuperscript{10} This was then promptly communicated to physicians, which led to many therapeutic changes. The incidence of pain decreased significantly in the intervention group (63\% vs. 42\%, $p=0.002$). The duration of mechanical ventilation was greatly reduced (120 vs. 65 hours, $p=0.01$); similarly, the incidence of nosocomial infections decreased from 17\% to 8\% ($p<0.05$). This was confirmed in a subsequent propensity-adjusted cohort study in which pain assessment on day 2 of hospitalization was associated with a shorter duration of mechanical ventilation (8 vs. 11 days, $p<0.01$) and shorter duration of stay in the ICU (13 vs. 18 days, $p<0.01$).\textsuperscript{11}

The ideal pain scale for assessment should be valid, reliable, and feasible. Given that there is currently no known or readily available objective biological measure to assess pain, the gold standard for assessment is patient self-report. In the ICU, some patients are communicative and able to report pain, even if they are unable to verbalize because of the presence of an endotracheal tube. In these patients, common self-report pain scales can be used. However, the self-report scale used must consider the method of nonverbal communication and the patient’s motor skills (e.g., ability to write or gesture). In most patients, communication is not possible; thus, pain must be assessed by observing patient behavior. According to the Society of Critical Care Medicine guidelines, pain should typically be assessed at least four times every nursing shift (e.g., every 3 hours) and as needed such as before, during, and after procedures, as well as before and after the provision of analgesics.\textsuperscript{1} Note that vital signs can only serve as a cue to further assessment using a validated scale and should not be used as the sole assessment to base treatment decisions. This is because hemodynamic measures such as blood pressure and heart rate are nonspecific to pain and are unreliable
measures in the ICU.\textsuperscript{12}

**Communicative Patients**

Before choosing the correct pain assessment tool, critically ill patients should be evaluated for their ability to interact using verbal or nonverbal communication. The pain scale chosen may need to change in the course of hospitalization. Early during ICU care, patients may be unable to communicate at all; however, as they progress, nonverbal communication may be possible, and after extubation, patients may be able to verbalize their pain. Commonly used self-report scales in the ICU setting include the Visual Analog Scale, which is available in a horizontal or vertical orientation (VAS-H or VAS-V); the verbal descriptor scale (VDS); and the numeric rating scale, which can be administered orally or visually (NRS-O or NRS-V). The VAS is a 10-cm line that is anchored at the ends with the words “no pain” and “extreme pain.” Patients then choose a point on the line that best represents their pain. Drawbacks of using this scale in the ICU include the need to measure distance on the line to calculate pain severity, ability to write with manual dexterity, and appropriate vision, which can often be impractical from a nursing perspective and challenging for patients. The VDS was derived from the Present Pain Index component of the McGill Pain Questionnaire.\textsuperscript{13} Although the number of verbal descriptors can vary, a 5-descriptor scale has been suggested as adequate.\textsuperscript{14} Patients are asked to choose from the phrase that best describes their pain, which includes “no pain,” “mild pain,” “moderate pain,” “severe pain,” and “extreme pain.” The NRS-O is perhaps the most common pain scale used in adult hospitalized patients. Patients verbalize a number from 0 to 10, which best represents their pain severity, with 0 being “no pain” and 10 being the “worst possible pain.” It is important that the clinician administering the NRS-O use consistent wording for the anchors to the scale because using different descriptions provided to patients has the potential to affect pain scores. Both the VDS and the NRS-O require verbal input from patients and thus may not be possible in many critically ill patients. One alternative in patients who are unable
to verbalize is a visual scale such as the NRS-V. This is an enlarged plastic laminated scale (e.g., 4 × 12 inches) anchored at opposite ends with 0 “no pain” and 10 “extreme pain” (Figure 6.1). Patients can then point to numbers directly on the scale or hold up the appropriate number of fingers indicative of their pain score with one or both hands. One study compared the use of these scales in 111 ICU patients who were communicative. The response rate measured before and after analgesic use or painful procedure was highest for the NRS-V (91%), followed by the NRSO (83%), VDS (78%), VAS-H (68%), and VAS-V (66%). The authors concluded that the NRS-V should be the self-report tool of choice for assessing pain in ICU patients.

**Noncommunicative Patients**

In patients unable to communicate, observation of patient behaviors using a structured scale is possible with behavioral pain scales. Several scales have been developed for this purpose, including the Behavioral Pain Scale (BPS), BPS-Non-intubated (BPS-NI), Critical-Care Pain Observation Tool (CPOT), Nonverbal Pain Scale (initial or revised), Pain Behavioral Assessment Tool, and Pain Assessment Intervention and Notation. Of these scales, the BPS and the CPOT are considered the most valid and reliable for use in the ICU (Figure 6.1). Both scales include similar components of facial expression, body movements, and ventilator compliance. In addition, the CPOT includes an evaluation of muscle tension. One advantage of the CPOT is that it can be used in patients who are not intubated by including an assessment of vocalization. The BPS was adapted to the BPS-NI for this purpose, but it has been evaluated in only 30 patients; thus, more evidence is needed for the BPS-NI before widespread implementation. These scales can be successfully implemented in nursing practice; however, the routine use of behavioral pain scales in noncommunicative patients remains lower than anticipated. In one investigation that included a survey of more than 800 nurses, the use of self-report pain scales was 89%, but in patients who could not communicate, the use of an assessment tool was only 33%. Thus, a concerted effort is needed
to increase the adoption of behavioral pain scales into clinical practice. In addition, it is important to emphasize that in some patients, such as those with motor function impairments (e.g., pharmacologic paralysis), these scales cannot be used because scoring depends on facial expressions such as grimacing, patient movement, and ventilator compliance, which require intact motor function. In these patients, deep sedation and aggressive analgesia should be provided. In addition, these scales have not been validated in patients with brain injury. Behavioral responses that may be atypical and an altered level of consciousness complicate pain assessment in these patients. However, studies suggest that even patients in an apparent vegetative state are able to perceive pain. Thus, it is reasonable to err on the side of treatment when routine assessment methods may be unreliable.

TREATMENT APPROACH AND ANALGOSEDATION

The management of pain and agitation are interrelated. Traditionally, agitation has been primarily managed with the use of sedatives such as propofol, dexmedetomidine, and benzodiazepines. Recent guidelines recommend that, in most patients, a light level of sedation be maintained and titrated to an appropriate sedation scale (see the chapter on sedation for more details). However, this agitation is often the result of underlying pain and discomfort. Although most sedatives can decrease consciousness, they have no analgesic effects (except for ketamine and dexmedetomidine); however, at high doses, central nervous system (CNS) depression may suppress the response to pain and the resulting agitation. This approach leads to more sedative use than necessary and contributes to producing a deep level of sedation. But sedative use may be associated with a greater risk of adverse effects such as hypotension with higher doses of propofol. It is also known that use of sedatives, especially benzodiazepines, may increase the risk of delirium and result in poor patient outcomes, including increased length of mechanical ventilation and duration of stay. An alternative approach, called analgesia-first or analgozedation, is used when agitated patients are given an analgesic first, and the sedative is
used as a rescue agent. International guidelines from the Society of Critical Care Medicine suggest that analgesia-first sedation is preferred to traditional sedation in mechanically ventilated patients.\(^1\) However, this was given a weak recommendation because of moderate-quality evidence, suggesting that although this method can be considered, more evidence is needed before routine implementation.

Some open-label trials, most of which have been conducted in Europe, have compared an analgesia-first approach with a traditional sedation-based approach.\textsuperscript{22} Advantages of the analgesia-first sedation included decreased days of mechanical ventilation, decreased ICU length of stay, and improved sedation-agitation scores.\textsuperscript{23-26} However, there was more agitated delirium in one study.\textsuperscript{26} Most studies evaluating analgosedation have been conducted using remifentanil. However, in one trial, fentanyl was comparable to remifentanil using this approach.\textsuperscript{27} In this trial, patients in the remifentanil group had greater pain after opioid discontinuation, which may have occurred because of the quick offset of effect from this agent. Currently, given the high cost of remifentanil in the United States, the use of fentanyl is an acceptable alternative in the ICU. Other concerns also remain with this approach because higher doses of opioids affect bowel motility and respiratory function. In addition, the risk of opioid withdrawal on discontinuation of higher prolonged doses should be anticipated. A logistical issue with this approach is also a greater effect on nursing resources. In one study, a 1:1 nurse/patient ratio was used to keep patients calm and avoid sedative provision until necessary.\textsuperscript{26} One suggested approach using an analgosedation technique is provided in Figure 6.2. There is no consensus regarding certain parameters such as bolus doses to be used, trigger doses to provide sedation, or maximum infusion rates. Figure 6.2 is based on the trial protocol used in the study by Muellejans et al.,\textsuperscript{27} but it can be adapted to suit institutional requirements and provider preferences.

**Table 6.1** Opioid Pharmacokinetics and Pharmacodynamics
THERAPEUTIC OPTIONS

Opioids

Given the severity of pain experienced by the critically ill population, opioids remain the analgesic agents of choice in the ICU. At this time, no comparative studies show that any one opioid is preferred to the others. Thus, therapy is selected according to the pharmacokinetic and pharmacodynamic characteristics of the opioid, patient history, comorbidities, adverse event profile, cost, and availability. Characteristics of commonly used opioids are listed in Table 6.1, and common adverse effects are listed in Figure 6.3. The most appropriate route for administering opioids in the critically ill population is the intravenous route. This is because of unpredictable and inadequate absorption by the gastrointestinal (GI) tract when mesenteric perfusion may be suboptimal. In addition, the intravenous route allows for the most rapid onset of effect and drug titration. This is crucial because
severe pain should be treated as quickly as possible. The difficulty of predicting analgesic requirements in these patients necessitates the ability to respond rapidly by altering or providing additional doses. Typically, pain is first controlled by the repeated use of bolus doses to achieve adequate serum and CNS concentrations while initiating a continuous infusion as maintenance therapy. This strategy has been used in trials comparing analgesia-based regimens in the ICU. Because of the shift in care toward analgosedation, intubated patients should receive a continuous opioid infusion, with few exceptions.
**Figure 6.3** Opioid adverse effects.

IgE = immunoglobulin E.
Some unique issues pertaining to commonly used opioids are important to discuss because they are commonly encountered during clinical care. For instance, morphine has always been the gold standard to which other opioids have been compared. However, it requires renal elimination and has active metabolites, which can lead to drug accumulation in patients with renal dysfunction. Renal function often fluctuates in the critically ill population, and some degree of impairment is common, especially in older adult patients or those receiving concurrent nephrotoxic therapies. Thus, continuous infusions may lead to prolonged effects even after drug discontinuation. This has the potential to increase time on mechanical ventilation and ICU length of stay. On the contrary, isolated bolus doses of morphine are unlikely to be problematic in this regard. The duration of effect of opioids is a function of several factors that include hepatic metabolism, presence of active metabolites, distribution and accumulation within deep tissue, and renal elimination. Hence, even more lipophilic opioids such hydromorphone and fentanyl may have prolonged effects after sustained use because of accumulation within fatty tissue or organ dysfunction. Another disadvantage of morphine is its histamine-related effect on blood pressure, which is of concern in patients with hemodynamic instability. But this is more likely to occur when large doses are given as a rapid infusion. Hence, using a continuous infusion of morphine is still considered appropriate in patients who are hypotensive. Using synthetic opioids such as fentanyl has become more popular among ICU clinicians because of their rapid onset of effect, lack of effect on blood pressure, few adverse effects, and relatively low accumulation with organ dysfunction. However, high bolus doses of fentanyl (e.g., 3–5 mcg/kg) have been associated with chest wall rigidity, particularly during anesthesia. Fortunately, this risk is minimal in the ICU, where bolus doses are usually 1–2 mcg/kg. Other common adverse effects of opioids include central nervous and respiratory depression, constipation, and nausea and vomiting. Tolerance to constipation does not develop, and most patients in the ICU should be given a stimulant or osmotic laxative on a scheduled
basis. Given the high incidence of constipation, it is better to err on the side of treatment, holding the laxative only if the patient develops diarrhea.\textsuperscript{32} Unless patient-specific circumstances warrant an alternative approach, it is reasonable to use fentanyl as the first-line opioid analgesic infusion in most patients.

**Non-opioids and Multimodal Therapy**

A multimodal analgesia approach involves the simultaneous use of two or more analgesic agents with different therapeutic mechanisms such that the effect is synergic.\textsuperscript{33} This also has the potential to minimize dose-related adverse effects by reducing the extent of exposure to any one agent. Opioids serve as the mainstay of treatment in this patient population, but use of opioids alone targets only mu-opioid receptors, allowing nociceptive transmission by other pain pathways. In the critically ill population, this approach usually incorporates non-opioids such as acetaminophen and nonsteroidal anti-inflammatory agents (NSAIDs). Adding agents such as gabapentin and carbamazepine can be beneficial when neuropathic pain is present. Regional blocks, local anesthetics, and epidural analgesia can also complement systemic opioid therapy when indicated. Pharmacologic characteristics of commonly used non-opioids are listed in Table 6.2.

| Table 6.2 | Non-opioid Characteristics |
Much of the evidence for multimodal analgesia is from studies conducted in non-critically ill postoperative patients or those with chronic pain. Benefits include reduced postoperative pain, decreased opioid consumption, and improved participation in physical therapy. The American Pain Society suggests this approach for managing acute and chronic pain, but there is a relative lack of evidence in the critically ill population. However, there are challenges to using a multimodal approach in the ICU because some non-opioid adjunctive agents must be given by the oral route because of dosage form availability. Some non-opioid agents also have unique adverse effects and drug interactions that need to be considered.
Acetaminophen used for this purpose is appealing and may be administered by the enteral or rectal route, but drug absorption may be unpredictable. In some situations, enteral administration is not possible, in which case rectal suppositories may be used. But the patient needs to be turned for rectal administration; this is a procedure that itself is painful, mitigating some of the benefit of the analgesic. In addition, the drug dose is lost with bowel movements, precluding this route in patients with diarrhea. The availability of an intravenous formulation has made this a suitable option in patients for whom these former routes are not feasible. In one randomized controlled trial conducted in Turkey, using intravenous paracetamol 1 g every 6 hours in postoperative ICU patients was associated with decreased pain, decreased opioid consumption, shorter time to extubation, and less nausea and vomiting. But this was a small study of only 40 patients, and the opioid used was meperidine; this agent, which is no longer recommended for analgesia in the critically ill population, may have accentuated the differences between groups. Thus, this study limits extrapolation to common practice in the United States, especially when using an analgosedation approach with an opioid such as fentanyl. Also of concern is that, in one study in Europe, an intravenous paracetamol product was associated with a clinically relevant decrease in systolic blood pressure in 33% of the patients, and 16% overall required some intervention such as a fluid bolus or vasopressor administration to correct hypotension. The mechanism for this effect on blood pressure is unknown.

Nonsteroidal anti-inflammatory drugs are also readily available in a variety of dosage forms that can be given by the oral, rectal, or intravenous route (e.g., ibuprofen, ketorolac). In postoperative patients after coronary artery bypass, using diclofenac given rectally was associated with decreased time to extubation, inotropic use, and rescue analgesic use. However, the method of opioid provision between the treatment arms was different, making it difficult to ascertain the effect of the NSAID alone. Of note, NSAIDs may be associated with adverse effects such as renal failure, GI bleeding, and interference with bone healing. This may be particularly problematic
in patients who are already on concurrent nephrotoxic therapies or medications such as antiplatelets and anticoagulants, which can predispose them to bleeding. The occurrence of organ failure is multifactorial and related to the underlying diagnosis (e.g., sepsis); using NSAIDs in these circumstances can exacerbate an already tenuous situation. Thus, adding NSAIDs needs to be individualized, weighing the individual risks versus the benefits. As a rule, if a nonopioid analgesic is being considered for multimodal therapy in the ICU, it is reasonable to consider oral acetaminophen first in most patients before NSAIDs.

Agents for Neuropathic Pain

Neuropathic pain originates from pathology of the nervous system. Although neuropathy is commonly associated with conditions such as diabetes and shingles, it can occur with nerve damage caused by trauma or surgery. All patients with injuries or surgery likely have some neuropathic component to their pain. Voltage-gated sodium channels play an important role in pain transmission, leading to the effectiveness of certain drug therapies such as carbamazepine and gabapentin, which stabilize these channels. Studies in the ICU have been conducted in patients with Guillain-Barré syndrome. In one trial, 12 critically ill patients with Guillain-Barré syndrome were given carbamazepine 100 mg every 8 hours or placebo by nasogastric tube in a randomized, double-blind, crossover design. Carbamazepine use was associated with lower pain scores and opioid requirements. This is a relatively old study, and the breakthrough opioid used was pethidine, which is no longer used. In another randomized three-arm trial in a similar population, patients were given carbamazepine 100 mg, gabapentin 300 mg, or placebo every 8 hours for 7 days. In this study, pain scores and opioid requirements were lowest in the gabapentin group during the study period. This trial more closely reflects clinical practice because fentanyl was used for breakthrough pain. This suggests that gabapentin is more suitable in the critically ill population. Carbamazepine is metabolized by cytochrome P450 (CYP) 3A4 and is susceptible to drug interactions with medications commonly
used in the ICU. In addition, carbamazepine is associated with serious dermatologic reactions such as toxic epidermal necrosis and Stevens-Johnson syndrome, requiring immediate discontinuation if a rash occurs. Patients with Chinese ancestry are at high risk of these serious dermatological conditions if they carry the genetic variant of the HLA-B gene, HLA-B*1502. Because of its reduced efficacy compared with gabapentin and its potential for drug interactions and serious adverse effects, carbamazepine should not be used first line. An important consideration is that in both of these studies, pain scores were self-reported; thus, the results pertain to a subset of patients who were able to communicate. Ideally, a larger study in the ICU that includes a broader population of postoperative patients would help establish the role of gabapentin and other anticonvulsant therapies in the critically ill population. Studies evaluating the use of gabapentin for postoperative pain have shown benefits, but this can depend on the type and extent of surgery done. In most of these studies, gabapentin was used preoperatively and continued for a few postoperative days. At this time, it is reasonable to consider the use of gabapentin 300 mg every 8 hours in patients at risk of neuropathic pain, particularly in those who have escalating opioid requirements.

Ketamine

Ketamine is an N-methyl-d-aspartate (NMDA) antagonist with analgesic and dissociative properties. It is most commonly used in the emergency department setting for procedural sedation, induction for rapid sequence intubation, and refractory bronchospasm. For procedural sedation, it is provided as a bolus dose of 1 mg/kg and may be repeated in increments of 0.5 mg/kg to achieve a dissociative state. Ketamine is particularly appealing because it enables the provision of analgosedation with minimal risk of respiratory depression. In addition, in contrast to other commonly used anesthetics (e.g., propofol), ketamine use is associated with an increase in blood pressure and heart rate because of increased endogenous catecholamine release. Thus, it is suitable in patients with tenuous blood pressure readings who require a procedure in the ICU. Ketamine
should be reserved for more invasive procedures that require a state of dissociation. However, lower doses such as 0.2–0.3 mg/kg intravenously are less likely to cause dissociation and are opioid sparing, especially in trauma patients.44

There is great interest in the sustained use of ketamine as a continuous infusion for analgosedation in the ICU. However, there is very little evidence to guide clinicians regarding the risks, benefits, and strategies for implementing this approach. Case reports using continuous infusions of ketamine in the ICU have shown it to be effective in patients with refractory pain with escalating sedative and opioid requirements. The doses used in these cases varied greatly, ranging more than 10-fold. Only one randomized trial is available that evaluated ketamine for postoperative pain after abdominal surgery.45 In this study, patients were given a bolus of 0.5 mg/kg, followed by an infusion of 2 mcg/kg/minute for 24 hours; this was reduced to 1 mcg/kg/minute for the next 24 hours. Morphine consumption was lower in the ketamine group than in the control group (58 vs. 80 mg, p<0.05), but pain scores were similar. At this time, ketamine may be considered in patients with refractory pain and escalating opioid and sedative requirements. Once initiated, the duration of use should be kept to a minimum and reevaluated each day. Ketamine is known to be associated with hallucinations and psychosis, which usually occur after awakening from procedural sedation in adults—a term coined “emergence phenomenon.” Prolonged use may predispose patients to delirium; thus, prolonged infusions should be avoided for routine use until more evidence is available. When ketamine is used for refractory pain as a sustained infusion, it is reasonable to start at a dose similar to that used in the randomized trial described previously (2 mcg/kg/minute or 0.1–0.2 mg/kg/hour), titrated as needed. Although a maximum dose has not been established, a rate of 2 mg/kg/hour (10-fold higher) would be consistent with the high doses in case reports.

Nonpharmacologic Therapy

Melzack and Wall proposed the gate control theory of pain in 1965.46 They theorized that the substantia gelatinosa in the dorsal horn of the
spinal cord acted as a gate, modulating noxious stimuli from peripheral nerves. This serves as the basis for nonpharmacologic cutaneous interventions such as massage therapy in the critically ill population. For instance, using massage stimulates large-diameter nerve fibers that can potentially decrease pain by inhibiting the conduction of nociceptive stimuli from smaller nerve fibers. Stimulating higher brain centers that are associated with cognition and affect can prevent the transmission of pain from the periphery by descending inhibition. Thus, nonpharmacologic interventions such as music and relaxation can help alleviate pain by facilitating inhibitory neural pathways from the brain to the spinal cord.

Nonpharmacologic therapies for analgesia with the potential to be implemented in the ICU include massage, music, relaxation, and the provision of sensory and procedural information. Only a few studies evaluate the use of massage in the critically ill population. Massage interventions in trials have varied by anatomic site (e.g., hands, feet, limbs, back, shoulders, scalp), duration of massage, and number of episodes. In one pilot study in the ICU, the use of hand massage was considered feasible and was well accepted by patients. The intervention consisted of a 5-minute massage on the palm and back of the hand, repeated for each hand, and conducted three times within 24 hours of ICU admission. Alternatively, 30-minute periods have been used on specific locations such as the feet or according to areas of concern for the patient. This latter approach requires communication from the patient. For instance, although some of these trials were conducted in the ICU, they were done after extubation. Thus, extrapolation to those who are intubated or noncommunicative is difficult. The focus of these studies is not specific to pain and includes effect on anxiety and sleep. Interventions often include combination approaches that incorporate music and relaxation. Hence, the effect of massage alone is difficult to interpret. Most studies have small sample sizes and are hypothesis generating, but they generally support an effect on pain reduction and relaxation. Questions remain regarding whether nurses can do this because qualified therapists or investigators did interventions in the trials. Although touch is known to
be a form of communication for caring and comfort, personal interpretations can vary depending on cultural background, previous experience, and attitude of family and friends. It is unknown whether this would be harmful in patients with psychosis or delirium, who were excluded in studies. Caution should be exercised in those with injuries or wounds, which would be contraindications to massage depending on the anatomic area affected. Lubricants and aromatics (e.g., lavender oil) used during the massage can be problematic because of the possibility for dermatologic allergies. Although guidelines from the Society of Critical Care Medicine suggest that nonpharmacologic interventions are relatively benign, easy to conduct, and low in cost, this particular intervention has potential for harm if not conducted appropriately and is an additional task requiring nursing resources. If certified massage therapists are used, this intervention will indeed have an additional cost.

Studies evaluating the effect of music therapy on pain and opioid consumption are heterogeneous and are considerably varied in the effect of the intervention. In the subset of studies of postoperative patients, the pain reduction attributed to music therapy was modest (i.e., 0.5 points on a 0–10 scale), and there was no greater benefit when patients were able to select their own music. Postoperative morphine consumption was 1 mg less at 2 hours and 5.7 mg less at 24 hours after surgery in the intervention groups. It is difficult to extrapolate these findings to critically ill patients. Important questions remain regarding how and when music therapy can be incorporated. Another intervention evaluated in postoperative patients is the use of muscle relaxation techniques that were taught preoperatively. Relaxation decreases anxiety and muscle tension and distracts from pain. Relaxation interventions have focused on one anatomic location such as the jaw (e.g., letting the lower drop slightly, resting the tongue and lips, breathing slowly, without thinking about speaking) or using a systematic technique. In a systematic technique, the patient is asked to lie in a comfortable position in the bed with closed eyes, followed by sequential relaxation of each body part, starting from the feet and moving to the head. The process lasts 5 minutes and is
repeated three times. Both of these relaxation techniques were associated with better pain control. The challenge of incorporating this process in the ICU is that it would probably have to be taught after ICU admission, rather than preoperatively, given the often-emergent nature of critical illness. Both of these studies were conducted in non–critically ill postoperative patients.

Finally, it is important to communicate information related to future procedures, and the pain likely to be associated with them, to critically ill patients. This is possible depending on the cognitive ability and level of sedation of patients. In one meta-analysis, providing information before procedures was beneficial for pain and distress, but the effect was highly variable. It is uncertain how this can be extrapolated to patients in the ICU. However, communicating information to patients is ethical and considered the standard of care. This can enable patients to anticipate and cope with the procedure. However, some patients may amplify negative cognitive and emotional processes; this phenomenon, known as catastrophizing, may lead to a more painful experience and heightened anxiety. At this time, given the uncertainty of the evidence, it is reasonable to err on the side of providing patients with the appropriate information. Future studies are needed to determine whether patients with certain traits such as catastrophizing will benefit if they are provided with limited rather than complete information before procedures. Overall, nonpharmacologic therapy for pain in the ICU may be provided in addition to standard pharmacologic therapies such as opioids and non-opioid adjuncts. High-level evidence to support these interventions is lacking, but most of these interventions are relatively benign, are feasible, and have low cost if implemented in a manner that augments rather than disrupts nursing care. Ideally, a combination of therapies can be used that incorporates the use of touch, music, and relaxation.

**PROCEDURAL PAIN**

Procedures done in the ICU include chest tube removal, wound drain removal, endotracheal and tracheal suctioning, line insertion (arterial,
peripheral venous, and central venous), peripheral blood draw, turning, respiratory exercises, positioning, wound care, and mobilization. Most recently, a large prospective cross-sectional study included data from 4,812 procedures done in 3,851 patients from 192 ICUs in 28 countries. The study found that chest tube removal, wound drain removal, and arterial line insertion were associated with the highest pain intensity; median pain intensities measured on a 0–10 NRS were 5, 4.5, and 4, respectively, during these three procedures. The change from baseline pain was about a 2- or 3-point increase. However, less than 50% of patients routinely receive analgesia before procedures.

In addition, it is important that the timing of the analgesic be such that its peak effect occurs during the procedure. For instance, morphine has a peak effect occurring at 20 minutes or longer. Thus, patients will not benefit from morphine if the procedure is done too soon after drug administration. Fentanyl intravenous has a more rapid onset of effect within 1 minute and may be more suitable when the procedure is emergent. Of the common procedures previously listed, endotracheal suctioning may need to be done emergently. Moreover, in some situations, such as placement of arterial lines, physician availability can lead to logistical challenges. Waiting 20 minutes for morphine to have peak effect may not be feasible when the physician is ready at the bedside. In these circumstances, an analgesic with a very rapid onset of effect (e.g., fentanyl) is preferred. Clinical trials have not shown the superiority of one analgesic over another. In fact, an NSAID such as ketorolac 30 mg intravenously was comparable with morphine 4 mg intravenously when given before chest tube removal in cardiac surgery patients. Ketorolac was administered 60 minutes before the procedure, which is consistent with its peak effect. Even the most appropriate opioid dose to be used is unclear. For instance, one trial showed that morphine 2.5 mg intravenously was similar to 7.5 mg intravenously during painful procedures. It is reasonable to use a bolus dose of morphine 4 mg intravenously or fentanyl 50 mcg intravenously for most adult patients. This dose can be increased for those with prior pain conditions or those who are opioid tolerant. The dose may be repeated if proven insufficient during the procedure.
More-invasive procedures such as wound debridement, abscess drainage, and endoscopy should be treated differently because these require a state of unconsciousness. These patients require a deeper level of sedation in addition to analgesia. Ketamine is a valuable option in these circumstances, as described in the previous section. Alternatively, the level of sedation can be temporarily increased in those already receiving sedative infusions. This can be accomplished by giving a sedative bolus with an increase in the infusion rate. Patients may have several procedures during a day, and analgesic provision before each procedure may lead to several additional doses provided. If possible, it is beneficial to cluster procedures so that repeated doses are not needed.

**OPIOID CONVERSIONS**

Converting from one opioid to another may be necessary because of drug-related adverse effects, lack of effectiveness, changes in the route of administration, drug availability, and transfer to the general medical ward. The equianalgesic potency of commonly used intravenous opioids is provided in Table 6.1. It is widely accepted that fentanyl intravenous is 100 times more potent than morphine intravenous, whereas hydromorphone intravenous is 6–7 times more potent than morphine intravenous. According to a study comparing fentanyl with remifentanil, the initial doses used and the mean doses required provide justification that fentanyl is 5–6 times more potent than remifentanil. Oral options in the ICU most commonly include morphine, hydromorphone, and oxycodone. Hydromorphone oral is 4 times more potent than morphine oral. This is different from the intravenous ratio between these agents, which is attributable to differences in bioavailability. Oxycodone oral is considered 1.5 times more potent than morphine oral, although it may be equivalent to morphine in some patients. Methadone is another option, which is considered in patients with refractory pain or to prevent opioid withdrawal. However, conversion ratios with methadone are not
constant but change, depending on the previous opioid dose used. In general, conversions to methadone should not occur in the ICU. Rather methadone is used as add-on therapy, and most adults can be initiated at a dose of 5–10 mg every 8 hours. This strategy will help minimize errors and will be acceptable for most patients in whom this agent is deemed essential.

When considering these ratios, it is important to understand where the evidence for these values came from. Most studies were conducted in patients with chronic pain conditions such as cancer pain or were single-dose trials. This was necessary for study designs because the validity and calculation of a ratio depended on a stable pain condition. In the ICU, pain is dynamic and changes during the course of critical illness. Pain and opioid requirements are anticipated to decrease as patients recover; thus, opioid use trends are more important than absolute values. Moreover, the ratios represent the mean values from studies. On closer inspection, opioid conversion studies show a considerable range around these mean values. Thus, there is likely to be great interpatient variability during the switching process. It is imperative that the risk of undertreatment be weighed against the risk of dose-related toxicity. In an intubated patient, higher calculated infusion rates may be acceptable because the risk of respiratory depression is mitigated by the fact that the patient is mechanically ventilated. However, after extubation, the risk-benefit ratio changes, so it is safer to err on the conservative side. Equianalgesic conversion ratios serve as a starting point for dose selection. Appropriate and timely drug titration to patient comfort is more important than the initial dose selected.

**TRANSITION FROM ICU TO WARD**

Typically, continuous opioid infusions are not permitted outside the ICU setting. This is because of fewer resources on general medical wards such as monitoring equipment and an increase in nurse/patient ratios. Moreover, after extubation, using continuous opioid infusions is risky. Thus, although bolus doses of opioids can be used for breakthrough
pain during this transition, patients must be converted to oral or enteral opioids and other adjunctive analgesics to meet baseline requirements as they are transferred to a general ward. One strategy is to use enteral opioids, when feasible, during the ICU stay (e.g., oxycodone immediate release) at scheduled intervals while decreasing opioid infusions each day. Sustained-release products cannot be crushed or given by feeding tubes, and the dynamic and fluctuating course of pain and analgesic requirements in the critically ill population makes this dosage form less desirable. There is little evidence regarding the best practice for this approach, and selection of the opioid, dose, and titration has not been formally evaluated. It is reasonable to start by providing 10%–20% of the total daily dose by the enteral route (divided and administered every 4–6 hours) using an equianalgesic ratio. The opioid infusion can simultaneously be decreased by a similar amount. An important consideration is that pain is anticipated to decrease over time; hence, opioid requirements should decrease rather than increase during the ICU stay. As the daily opioid provision is reduced, it is important to monitor for withdrawal, which is more likely to occur with rapid de-escalation in patients who received higher doses of opioids for extended durations. An additional opioid bolus may be needed, or the drip rate may have to be temporarily increased. Patients may be eligible for a trial off the opioid drip when the rate is tapered to a minimum of 25 mcg/hour of fentanyl intravenous equivalents, with adequate pain control and no signs of withdrawal.

In patients with or at risk of withdrawal, one strategy is to use enteral methadone. Methadone is an NMDA antagonist and may benefit opioid-tolerant patients. Hence, even small doses may have profound effects on opioid requirements. Using methadone for this purpose has primarily been evaluated in the pediatric patient population. In one prospective cohort study, most pediatric patients with symptoms of withdrawal successfully completed a 10-day methadone weaning protocol. The protocol involved converting previous 24-hour fentanyl use to an equivalent oral morphine dose and then converting the patient to methadone. However, these patients did not require mechanical ventilation at the time of enrollment, limiting extrapolation to this patient
subset. Using oral morphine as an intermediate step may be unnecessary, and the complexity of the calculations may result in medication errors. In a randomized controlled trial involving 78 pediatric patients who were on prolonged fentanyl infusions, patients were randomized to a low-dose methadone strategy or a high-dose strategy. Patients in the low-dose group were given a 0.1-mg/kg/dose (e.g., a 10-kg patient would receive a 1-mg/dose irrespective of fentanyl infusion rate). The high-dose group was given a 0.1-mg/kg/dose multiplied by weight and fentanyl infusion rate (e.g., a 10-kg patient receiving fentanyl 3 mcg/kg/hour would receive a dose of 3 mg). Methadone was given every 6 hours for the first 24 hours, followed by every 12 hours for the second 24 hours, followed by daily use for the next 10 days, during which the dose was decreased by 10% each day. The fentanyl infusion was tapered off within 72 hours of the first dose of methadone. There was no significant difference in the proportion of patients who completed the methadone taper successfully in the low- and high-dose groups (56% vs. 62%, p=0.79; respectively). Because of these results, complexity of the protocol, and feasibility of implementation, it is reasonable to use a low-dose strategy when methadone use is being considered in the pediatric patient population. Although similar studies have not been conducted in adults, a similar taper using 5–10 mg of methadone given every 8 hours as a starting dose is a reasonable approach for most patients. Given that the ratio between methadone and morphine changes according to the amount of previous morphine use, the methadone dose required varies very little, and a fixed-dose strategy (e.g., starting at 10 mg every 6 hours; then taper) is acceptable. Methadone use has been associated with corrected QT (QTc) interval prolongation. This can be particularly problematic in patients with a high baseline QTc or those on concurrent medications that prolong the QTc. Thus, methadone use should be avoided unless necessary, and if used, electrocardiogram monitoring is required during therapy.

It is also important to optimize the use of non-opioid adjunctive analgesics as described in the previous section during transition to the ward. This will reduce opioid requirements and work synergistically for
pain control. Although no evidence suggests which patients are likely to have poor pain control during transition to the ward, patient history and ICU course will likely help target patients at risk. Specific variables to consider include pain control in the ICU, opioid requirements, rate of opioid de-escalation, time between when opioid infusion was terminated and transfer, surgical procedures, injuries, chronic pain conditions, and psychiatric illness.

**SUMMARY**

Pain is ubiquitous in the ICU, and treatment of pain is essential and humane. Appropriate and routine pain assessment using validated scales such as the NRS-V for communicative patients or the BPS and CPOT for noncommunicative patients is the first step toward better pain management and improved patient outcomes. Opioid analgesia is the mainstay of treatment given the severity of pain experienced in the ICU; however, non-opioid adjuncts and nonpharmacologic therapy may be used as part of a multimodal approach. Although more evidence is needed, an analgosedation strategy is preferred to the traditional sedative-based approach to managing patient comfort. Clinicians should be mindful of the important pharmacologic considerations during procedures, opioid conversions, and transitions of care that occur when patients are transferred from the ICU to the general ward.

LEARNING OBJECTIVES

1. Define and characterize agitation in critically ill patients.
2. State the estimated incidence of agitation in the intensive care unit.
3. Identify the etiology of agitation, including patient-related, illness-related, and environmental factors.
4. Describe the clinical significance of agitation.
5. Discuss the importance of routinely assessing comfort, and compare subjective and objective monitoring techniques.
6. Summarize nonpharmacologic interventions used to treat and prevent agitation.
7. Compare and contrast the pharmacologic agents used to provide comfort.
8. Develop an evidence-based, patient-specific approach to providing comfort.

ABBREVIATIONS IN THIS CHAPTER

BIS    Bispectral index
INTRODUCTION

Agitation in the intensive care unit (ICU) is common and distressful for patients, families, and caregivers. It is often precipitated by instrumentation, unfamiliar surroundings, hemodynamic or metabolic derangements, pain, or the inability to communicate. Provision of evidence-based, humane care should include regular assessments of comfort, liberal treatment of pain, titration of sedation to a patient-specific goal, use of sedation protocols, and avoidance of coma. A multidisciplinary team is best suited to meet these ends. This chapter will provide a pragmatic review of agitation in the ICU with a focus on its incidence, etiology, significance, assessment, and management.

DEFINING AGITATION

There is no unanimously accepted definition for agitation. Definitions
typically include its psychomotor manifestations, which are often an expression of immense inner tension. Agitated patients generally have inappropriate, irrational, and counterproductive behaviors that are out of proportion to the situation.¹,² Nonpurposeful behaviors are common (e.g., thrashing), but so are purposeful ones (e.g., deliberate attempts to remove an endotracheal tube). Agitation caused by delirium (i.e., hyperactive delirium) is a distinct diagnosis and is examined in detail in the Delirium chapter.

Agitation may be best defined using bedside descriptors. Commonly used terms include restlessness, pulling at medical devices, overbreathing the mechanical ventilator, moving from side-to-side, rambling, shouting, or moaning.³,⁴ Many of these descriptors have been incorporated into subjective sedation scales, which will be examined in greater detail later. Although most experienced caregivers can identify agitation, a universally accepted definition would be helpful.

INCIDENCE

Agitation may occur in 16%–71% of critically ill patients.⁴-⁸ Variability in the reported incidence is because of heterogeneity in descriptive studies. Differences include the patient population, definition of agitation, study design, and methods of assessing and providing comfort. Regardless of its exact incidence, agitation is an important source of discomfort for patients, families, and caregivers.⁹

Agitation typically begins within 4 days of ICU admission and is most severe within the first few days.⁴,⁶,⁸ About 43% of agitated patients will be so on admission, and 40%–86% will be agitated within the first 24 hours.⁵-⁸ Early-onset agitation may be a result of acute illness, pain, instrumentation, or an unfamiliar environment. About 75% of patients will be agitated for several days.⁴,⁶,⁸ Agitation occurs at a similar rate at night and during the day, which may be because of sundowning or disturbances in the sleep-wake cycle.⁶,⁸ Overall, it can arise throughout an ICU admission and is typically because of several interrelated factors.
ETIOLOGY

Identifying the cause of agitation can help guide corrective efforts. No study has used self-report to elucidate its etiology because patients are often too encephalopathic to provide usable information. In addition, they are often unable to communicate because of medication effect or the presence of an endotracheal tube. Pathophysiologically, agitation may be caused by excessive sympathetic neurotransmission, dopaminergic hyperactivity, changes in pain sensation, or hypothalamic-pituitary-adrenal axis dysfunction. The etiology is often multifactorial with contributions from patient-related, illness-related, or environmental factors.

Patient-Related Factors

Medical comorbidities often cause agitation or predispose patients to developing it. Pain may be present in more than 50% of ICU patients and has been identified as a considerable cause of anxiety. Psychiatric illness and psychoactive drug use have also been associated with agitation. Cognitive impairment, present in 6%–42% of ICU patients, has been implicated, and more than half of physicians are unaware that patients have this deficit at baseline. Kidney and liver failure can cause metabolic encephalopathy with associated restlessness. Nicotine dependence, present in 22%–46% of ICU patients, may increase the risk of agitation by 3-fold. Alcohol and substance abuse disorders can be found in 39% of ICU patients and are associated with greater sedative and analgesic requirements. The association between age and agitation remains unclear.

Home medications and those initiated in the ICU can also cause agitation. Reinitiation of home psychoactive medications, when clinically appropriate, can prevent withdrawal-induced discomfort. On the other hand, drug-induced agitation may occur with agents initiated in the ICU, including central nervous system (CNS) stimulants (amphetamines or modafinil), glucocorticosteroids, anticholinergics, serotoninics, opioids, antimicrobials (cefepime or fluoroquinolones), histamine-1 (H1)-
or H\textsubscript{2}-receptor antagonists (famotidine, ranitidine, or diphenhydramine),
dopaminergics (amantadine or bromocriptine), sedatives (ketamine,
benzodiazepines, or propofol), and volatile anesthetics.\textsuperscript{23-26} Readers
are encouraged to review more comprehensive sources on drug-
induced agitation.\textsuperscript{27,28}

**Illness-Related Factors**

Acute illnesses can increase the risk of developing agitation. Respiratory failure and hypoxemia (Pao\textsubscript{2}/Fio\textsubscript{2} ratio less than 200) have been implicated.\textsuperscript{4,5} Acidosis has also been correlated with agitation.\textsuperscript{5,7,29} Febrile patients may be 4.5 times more likely to develop agitation.\textsuperscript{4,6,29} Sepsis-associated brain dysfunction, present in up to 70\% of patients with sepsis, can manifest as agitation.\textsuperscript{4,8,30} Meningitis, encephalitis, and urinary tract infections can do so as well. Neurological insults including strokes, brain abscesses, cerebral malignancies, and seizures can provoke agitation.\textsuperscript{3} Delirium, especially the hyperactive or mixed variant, can cause periodic aggression.\textsuperscript{31} Electrolyte abnormalities (hypernatremia, hyponatremia, hypokalemia, or hypermagnesemia) may also play a role.\textsuperscript{8,29}

**Environmental Factors**

Routine aspects of care to providers are far from the norm for ICU patients. Mechanical ventilation and the endotracheal tube are one of the most common causes of distress.\textsuperscript{32} About one-half of mechanically ventilated patients recollect anxiety, fear, pain, and the inability to talk.\textsuperscript{32,33} Likewise, about one-third report discomfort associated with secretions, difficulty sleeping, panic, choking, and not getting enough air.\textsuperscript{32,33} In addition, ventilator dyssynchrony can cause insecurity, fear, and lack of sleep.\textsuperscript{33} Vascular access and feeding tubes are other notable causes of apprehension.\textsuperscript{12,13}

Patients report that the following are the most prominent stressors in the ICU: pain, sleep deprivation, instrumentation, loss of control, restraints, receiving no explanations of treatments, not knowing when
things will be done, thirst, and having the lights on constantly.\textsuperscript{9,12,13,34} Caregivers should remember that pain can occur at rest and during routine procedures like dressing changes, turning, suctioning, and chest tube removal.\textsuperscript{35-37} Accordingly, liberal treatment of pain is imperative.\textsuperscript{38}

Excessive noise is also a stressor in the ICU.\textsuperscript{9,12,13} Sound levels almost always exceed the 35 average A-weighted energy-equivalent sound pressure in decibels (dBA L\textsubscript{Aeq}) limit set by the World Health Organization.\textsuperscript{39,40} Peak levels are similar to that of heavy traffic (85 dBA), and they continue to rise each year.\textsuperscript{40,41} Excessive sound can cause sleep deprivation and altered sleep-wake cycles, which are common causes of stress and delirium.\textsuperscript{42} Systematically assessing patient-related, illness-related, and environmental precipitants of agitation is the first step in providing comfort in the ICU.

**CLINICAL SIGNIFICANCE**

The clinical impact of agitation reportedly ranges from minor discomfort to increased mortality.\textsuperscript{43,44} Most reports fail to capture the potential psychological impact of agitation on patients, families, and caregivers and its post-ICU implications. An appreciation for its significance may serve as an impetus to better understand its causes, treatment, and prevention.

The outcome most commonly associated with agitation is medical device removal. Removal of minimally invasive devices such as oxygen masks, wound dressings, or cardiac monitors increases nursing workload, whereas the removal of invasive devices such as peripherally inserted or central catheters, arterial catheters, endotracheal tubes, or surgical drains may lead to significant morbidity.\textsuperscript{45,46} Agitation may be present in 58\%-74\% of patients preceding device removal, and inadequate analgesia and sedation has been implicated in about 30\% of cases.\textsuperscript{45,46}

Self-extubation is the most well-known form of medical device removal.\textsuperscript{47-52} Restless or agitated patients may be 5.5 times more likely to self-extubate than those who are calm.\textsuperscript{50} It may occur more commonly in patients receiving no sedation (opioids only) compared
with those receiving intermittent or continuous sedation, although data are conflicting.\textsuperscript{52,53} Reintubation may be required in 22\%–78\% of these patients.\textsuperscript{51,52} Unplanned extubation has been associated with longer ICU and hospital length of stay (LOS), prolonged mechanical ventilation, and a greater likelihood of being transferred to a long-term care facility.\textsuperscript{50,51,54} Negative sequela are largely driven by patients who require reintubation.\textsuperscript{51,54}

Agitation can also cause maladaptive physiologic effects. Catecholamine concentrations, which are typically elevated in critically ill patients, are further increased by agitation.\textsuperscript{55-58} Resultant tachycardia can exacerbate myocardial ischemia and, when sustained, is associated with longer ICU LOS and major cardiac events.\textsuperscript{55,59} Blood pressure elevations can be catastrophic in patients with intracerebral hemorrhages or aortic dissections. Agitation may also lead to clenching and excessive peripheral muscle metabolism and lactate production.\textsuperscript{10} Similarly, systemic and myocardial oxygen consumption increases when sedation is withdrawn or when weaning from mechanical ventilation fails.\textsuperscript{60,61}

Many other negative outcomes have been associated with agitation. An increase in nosocomial infections may occur because of the immunosuppressant effects of sedatives, but it is more likely the result of an increase in ICU LOS and mechanical ventilator duration that accompanies oversedation.\textsuperscript{8,62,63} The influence of agitation on ICU LOS and duration of ventilation varies, but they are probably prolonged because of increased sedation administration, greater infection risk, and the need to taper pharmacotherapy before transferring to a non-ICU bed.\textsuperscript{5,7,8} It may also lead to a greater workload for caregivers.\textsuperscript{8} Ameliorating agitation’s negative physical and psychological responses can improve outcomes and help patients and families adapt to the ICU environment.

---

**ASSESSING AGITATION AND SEDATION**

The value of systematically monitoring patient comfort cannot be overstated. Regular assessments may reduce the incidence of severe
agitation by 59%; decrease the amount of sedatives, analgesics, or vasoactive drugs administered; and reduce nosocomial infections and duration of mechanical ventilation. Monitoring can be accomplished with subjective sedation scales (e.g., Sedation-Agitation Scale [SAS] or Richmond Agitation-Sedation Scale [RASS]) or objective measures (e.g., bispectral index [BIS] or continuous electroencephalography [EEG]). Large-scale implementation of comfort monitoring is feasible and highly encouraged.

The 2013 Society of Critical Care Medicine (SCCM) pain, agitation, and delirium (PAD) guidelines suggest that comfort should be assessed at least four times per shift and as needed thereafter.

**Subjective Sedation Scales**

Subjective sedation scales help facilitate communication between caregivers, establish goals for sedation, and guide therapeutic options. Most can be completed in less than 2 minutes. Unfortunately, only half of caregivers routinely use them. Arousal is the central domain assessed by these scales. Because agitation and sedation are part of a continuum, subjective assessment scales should encompass coma to dangerous agitation.

Subjective sedation scales are evaluated according to their psychometric properties, which includes item selection, content validation, reliability, construct validity, feasibility, and impact on patient outcomes. Because no “gold standard” exists, validity (i.e., ability of the scale to accurately assess agitation and sedation) has been established with content validation and construct validity. In general, subjective sedation scales were developed using a variety of methods and are necessarily subjective in nature.

The 2013 SCCM PAD guidelines examined 10 subjective sedation scales. A subsequent study identified one more, bringing the total to 11: Adaptation to the Intensive Care Environment, Motor Activity Assessment Scale, Minnesota Sedation Assessment Tool, Observer’s Assessment of Alertness/Sedation, SAS, Sedation Intensive Care Score, New Sheffield Sedation Scale, Ramsay Sedation Scale, RASS,
Vancouver Interaction and Calmness Scale, and Nursing Instrument for the Communication of Sedation.\textsuperscript{72} Several other scales have been developed, but most lack the methodological quality for formal evaluation.\textsuperscript{73} The RASS and SAS have consistently performed well in studies that have evaluated their psychometric properties, and they are endorsed by the 2013 SCCM PAD guidelines.\textsuperscript{11,72}

**Ramsay Sedation Scale**

Before the SAS and RASS were conceived, caregivers and researchers used the Ramsay scale. Originally named the controlled sedation scale, the Ramsay scale was developed in 1974 to assess various depths of sedation (Table 7.1).\textsuperscript{74,75} Its biggest drawback is that it contains only one level of agitation, which makes it difficult to distinguish mild, moderate, or severe distress. Regardless, the Ramsay scale remains one of the most widely used subjective sedation scales worldwide.\textsuperscript{76}

**Sedation-Agitation Scale**

The SAS was developed in 1992 while evaluating continuous infusion haloperidol for ICU agitation.\textsuperscript{77} Riker and colleagues realized that there was no way to comprehensively describe agitation and sedation, so they developed a graded scale using bedside descriptors.\textsuperscript{75} A subsequent editorial urging the creation of subjective sedation scales prompted the investigators to revisit the SAS, and a revised iteration was published in 1999 (Table 7.2).\textsuperscript{68,78}

The SAS is centered around a score of 4 (calm and cooperative) and has seven tiers that range from 1 (unarousable) to 7 (dangerous agitation). It was initially validated against the Ramsay and Harris scales and later against the BIS and Visual Analog Scale.\textsuperscript{68,79,80} It has been studied in more than 1,500 patients and has been published in several languages.\textsuperscript{72} The salient feature of the SAS is that sedated patients (SAS score of 3) should be able to follow simple commands (e.g., open eyes, maintain eye contact, squeeze hand, stick out tongue, and wiggle toes).

1     Unarousable      Minimal or no response to noxious stimuli, does not communicate or follow commands

a Patients who are a SAS 1 or 2 should not be assessed for delirium. The scale should not be used for patients receiving paralytics. The SAS has not been validated in patients with neurological injury or those requiring medically induced coma (i.e., intracranial pressure elevations or status epilepticus).

Richmond Agitation-Sedation Scale

The RASS was developed in 1999 in an effort to create a scale that offered more distinction between levels of agitation and sedation (Table 7.3). The RASS is centered around zero (alert and calm) and has four levels of agitation (restless to combative) and five levels of sedation (drowsy to unarousable). It was originally validated against the Ramsay scale, Glasgow Coma Scale, Visual Analog Scale, and SAS. It was later validated against a geriatric psychiatrist and geriatric neuropsychologist and the BIS. The RASS has been studied in more than 3,400 patients and has been translated into several languages.

The RASS uses eye contact as a surrogate for arousal, content of thought, and ultimately consciousness. The biggest drawback of the RASS is that it does not examine patients’ ability to interact with their environment (i.e., wakefulness), which should be present when assessing pain, evaluating delirium, and determining whether a patient is a candidate for mobilization. Although there is no validated definition of wakefulness, following simple commands may be the most appropriate way to identify it.

Objective Monitoring
Objective measures of sedation can supplement subjective scales, make up for subjective scale shortcomings (e.g., need for motor responsiveness or patient cooperation), and partly address variations in sedation practices.\textsuperscript{82} Objective measures include vital signs, auditory evoked potentials, BIS, Narcotrend Index, patient state index, and state entropy. Use of vital signs should be avoided because they can nonspecifically fluctuate, and studies detailing their appropriateness are conflicting.\textsuperscript{83,84} Data describing the use of auditory evoked potentials, Narcotrend Index, patient state index, or state entropy are in their infancy.\textsuperscript{11} Of all the objective measures, the BIS is the most advanced.

The BIS interprets raw EEG signals by a proprietary algorithm to create a single number for level of consciousness ranging from 0 to 100.\textsuperscript{85} A major assumption is that cortical activity is reflective of consciousness.\textsuperscript{75} Other data analyzed include power spectral information, degree of EEG suppression, beta frequency activation, and synchronization with lower frequencies.\textsuperscript{86} Bispectral index scores can be interpreted as follows: 0 is complete EEG suppression, 1–40 is deep sedation, 41–60 is moderate sedation, 61–70 is light sedation, and 71–100 is light sedation to fully awake.\textsuperscript{71} Caregivers should be cognizant that the BIS is influenced by sleep, neurological disease, encephalopathy, cerebral ischemia, electromyography, hypothermia, genetically determined low-voltage patterns, placement of the leads, drugs, and sound.\textsuperscript{85,87,88}

</table>
+1 Restless Anxious or apprehensive but movements not aggressive or vigorous
0 Alert and calm
-1 Drowsy Not fully alert, but has sustained (> 10 seconds) awakening, with eye contact, to voice
-2 Light sedation Briefly (< 10 seconds) awakens with eye contact to voice
-3 Moderate sedation Any movement (but no eye contact) to voice
-4 Deep sedation No response to voice, but any movement to physical stimulation
-5 Unarousable No response to voice or physical stimulation

Patients who are a RASS -3 to -5 should not be assessed for delirium. The scale should not be used for patients receiving paralytics. The RASS has been validated in patients in a medical respiratory, neuroscience, coronary, surgical trauma, and cardiac surgery ICU. RASS should not be used in those requiring medically induced coma (i.e., intracranial pressure elevations or status epilepticus) or in those with severe auditory or visual impairments.

The BIS has been compared with several subjective sedation scales, but a consistent linear relationship between them has been elusive. Discrepancies may occur because the BIS tops out, whereas subjective scales bottom out (Figure 7.1). A BIS value less than 60 may be appropriate for deeper sedation, according to studies showing that surgical patients rarely recall their experience when values are less than 60. Overall, the BIS should be reserved for select ICU patients such as those requiring prognostication during

targeted temperature management, burst suppression to control intracranial pressure (ICP), neuromuscular blockade, or deep sedation for any other reason.\textsuperscript{90,91}

**NONPHARMACOLOGIC INTERVENTIONS**

Nonpharmacologic comfort measures can be used alone or in addition to pharmacologic agents.\textsuperscript{43} Data supporting their use are limited, but their benefits likely outweigh the risks. Intensive care unit survivors have reported that caregiver support, explanations, and a personal approach are vital to psychological well-being.\textsuperscript{92} Encouragement, allowing patients to write, and explaining care plans are viewed as stress-relieving. Responding slowly to call bells imparts feelings of helplessness and dependency.\textsuperscript{92} Caregivers are encouraged to explain what they are doing, even when they perceive patients as comatose.

Noise is a stressor that can be obviated with nonpharmacologic interventions.\textsuperscript{9,12,13} Noise-reducing strategies such as ear plugs, sound masking, and acoustic absorption have been evaluated with favorable results.\textsuperscript{93,94} Reducing noise with behavioral modification and source control may circumvent the need for other modalities.\textsuperscript{95} Patient-directed music therapy represents another potential way to reduce the burden of unpleasant sounds.\textsuperscript{96}

Several other nonpharmacologic strategies can be employed. Eye masks, light dimming, and rooms with windows represent ways of reducing bothersome artificial lighting. Manipulative medicine and physical therapy can be used to relieve pain.\textsuperscript{2,97} Routine procedures like bladder emptying and repositioning are also crucial. Physical restraints should be reserved for severe agitation (e.g., imminent harm to the patient or caregiver) because of ethical considerations, psychological distress (including the development posttraumatic stress disorder), and risk of delirium.\textsuperscript{98-101} Although nonpharmacologic interventions are sometimes successful, pharmacologic therapy will be needed more often than not.
Once unresponsiveness is achieved, subjective assessment tools like the SAS can no longer quantify sedation depth. Processed electroencephalographic monitors like the BIS can continue to quantify sedation depth all the way down to an isoelectric state. For example, when a patient has a SAS score of 1, providers cannot describe deeper sedation; however, the BIS can assess brain activity down to an isoelectric state.

Adapted with permission from: Fraser GL, Riker RR. Bispectral index monitoring in the intensive care unit providers more signal than noise. Pharmacotherapy 2005;25(5 pt 2):19S-27S.

PHARMACOLOGIC AGENTS

More than 50% of mechanically ventilated patients require sedation. Nonventilated patients occupy 60%–80% of ICU beds and often require sedation as well. Unfortunately, no ideal sedative agent exists, and no agent has been found to be universally superior to the rest. This section will review the pharmacology, pharmacokinetics, and appropriate clinical context for using opioids, traditional sedatives, and alternative agents.
Opioids

Opioids (fentanyl, hydromorphone, morphine, remifentanil, and methadone) are commonly used in the ICU for relief of pain and analgosedation.\textsuperscript{107} Analgosedation is a sedation strategy that targets pain and discomfort with analgesics before more traditional sedatives are introduced.\textsuperscript{108} All opioids are equally effective when titrated to patient-specific goals (Table 7.4).\textsuperscript{11} Opioids predominantly agonize mu-receptors, which results in analgesia, euphoria, and serenity.\textsuperscript{109} Class-wide adverse effects include tolerance, constipation, suppression of cough reflexes, respiratory depression, and hypotension; these effects occur especially with morphine, which induces histamine release and venodilation.\textsuperscript{110} The opioids are briefly discussed with a focus on analgosedation, and more information can be found in the Pain chapter.

Fentanyl

Fentanyl is a synthetic phenylpiperidine derivative and is one of the most commonly prescribed opioids in ICUs worldwide.\textsuperscript{102,104,109,111,112} It is about 100 times more potent than morphine.\textsuperscript{113} In general, it is given as an intermittent injection or continuous infusion. Transdermal patches should not be used for acute treatment of pain because of delayed onset and sporadic absorption; however, they may find utility when de-escalating care.\textsuperscript{114}

Only 10\% of fentanyl is excreted unchanged by the kidneys, and data supporting dosing adjustments with impaired renal function are low quality\textsuperscript{115,116} Fentanyl is lipophilic and can accumulate in adipose tissue, resulting in a prolonged duration of action with long-term use.\textsuperscript{110,117} As a substrate for cytochrome P450 (CYP) 3A4, fentanyl may interact with enzyme system inhibitors (e.g., azole antifungals, macrolides, protease inhibitors, or non-dihydropyridine calcium channel blockers) and inducers (barbiturates, phenytoin, rifampin, or carbamazepine). Some cases of fentanyl-induced serotonin syndrome have been described when combined with selective serotonin reuptake inhibitors.\textsuperscript{118,119} Fentanyl infrequently causes chest wall rigidity when large doses are administered rapidly.\textsuperscript{110} Overall, its favorable
pharmacokinetics/pharmacodynamics and cost profiles make it an attractive analgosedative.

**Hydromorphone**

Hydromorphone is a semisynthetic phenanthrene that is derived from morphine and is about 6.5 times more potent.\textsuperscript{109,113} Because of its relatively long half-life (2–3 hours) and prolonged time to steady state, bolus dosing is encouraged when initiating or titrating an infusion.\textsuperscript{11} Hydromorphone is metabolized to hydromorphone-3-glucuronide, which has been implicated in neurotoxic events in patients who receive high doses or have renal impairment.\textsuperscript{120,121}

Hydromorphone is an option for opioid rotation because it may restore analgesia and sedation in patients who no longer respond to high doses of other opioids. The mechanism by which opioid rotation restores analgesia is unknown, but it may be because of incomplete cross-tolerance, genetic polymorphisms, and interindividual differences in opioid receptor types, interactions, density, or binding.\textsuperscript{122} Data supporting this strategy are extrapolated from the oncology literature, where intravenous hydro-morphone has been used to manage intractable cancer pain in patients whose other opioids have failed.\textsuperscript{123,124} A 1- or 2-mg intravenous test dose can be given, and if a patient responds favorably, it can be scheduled, or an infusion can be initiated.

### Morphine

Morphine is the prototypical phenanthrene. Its use has steadily declined for several reasons. First, it is hepatically metabolized to the active metabolites morphine-3-glucuronide and morphine-6-glucuronide. The former can cause neurotoxicity and hyperalgesia, whereas the latter can cause oversedation. Second, morphine is hydrophilic, which results in a slow onset of action. Third, its metabolism and active metabolite elimination are
reduced in the setting of renal or hepatic impairment.\textsuperscript{115,130} Fourth, it is poorly titratable because of its long-half-life compared with other opioids. Finally, it induces histamine release, which can cause bronchospasm and venodilation.\textsuperscript{129} In general, other opioids may be safer analgosedatives.

**Remifentanil**

Remifentanil is a synthetic phenylpiperidine derivate with potency similar to fentanyl.\textsuperscript{109} Remifentanil contains an ester linkage, which is rapidly metabolized by nonspecific tissue and plasma esterases to inactive metabolites.\textsuperscript{117} Because of this, it has a short half-life (3–10 minutes) and duration of action regardless of infusion duration and end-organ function.\textsuperscript{131} This represents an advantage if frequent neurological evaluations are necessary, but it can be problematic as well.\textsuperscript{132} Withdrawal or resurgence of pain can occur if the infusion is abruptly or inadvertently discontinued.\textsuperscript{133} Rescue opioids should be immediately available. Despite many interesting characteristics, its use remains low across the globe.\textsuperscript{102,111,112,134}

Remifentanil is the most studied analgosedative and is an attractive option in brain-injured patients because of its predictable pharmacokinetics.\textsuperscript{132,135-141} It acts synergistically with propofol, inhaled anesthetics, and benzodiazepines.\textsuperscript{142} Hyperalgesia and withdrawal symptoms should be monitored for and can be diminished by administering longer-acting opioids during tapering.\textsuperscript{88,143} Ultimately, its safety and efficacy are similar to that of fentanyl, making the latter more used on the basis of cost, ease of use, and familiarity.\textsuperscript{138}

**Methadone**

Methadone is a synthetic diphenylheptane derivative that is unique from other opioids because it antagonizes N-methyl-d-aspartate (NMDA) receptors.\textsuperscript{109,144} Methadone’s relative potency compared with morphine is contingent on the duration of administration and tolerance.\textsuperscript{145} Its long half-life and tendency to prolong the QTc interval
limit its usefulness in the ICU.\textsuperscript{144,146} Total daily dose of methadone is the most established risk factor for QTc prolongation, but patients taking as little as 30–40 mg/day have developed torsades de pointes.\textsuperscript{146,147} Pharmacists should monitor for other risk factors for QTc prolongation, including electrolyte abnormalities (hypokalemia or hypomagnesaemia) and QTc-prolonging medications (e.g., fluoroquinolones, antipsychotics, amiodarone, or erythromycin).\textsuperscript{148}

Methadone can be used to facilitate the discontinuation of opioid infusions. A reasonable starting dose is 10 mg every 6–8 hours. It may reduce ventilator weaning time and obviate the need for continuously infused opioids, but its impact on ICU LOS, total opioid exposure, and duration of mechanical ventilation remains unclear.\textsuperscript{149,150} Methadone has also shown promise in the setting of opioid tolerance and hyperalgesia, which may be because of excessive NMDA receptor stimulation.\textsuperscript{151} Rotating to methadone from other opioids has been studied in the setting of intractable or cancer-related pain, but it has yet to be studied in the ICU for this indication.\textsuperscript{122}

**Traditional Sedatives**

**Benzodiazepines**

Benzodiazepines (midazolam and lorazepam) potentiate the activity of γ-aminobutyric acid (GABA) at \( \text{GABA}_A \) receptors, which increases chloride influx leading to neuronal hyperpolarization (Table 7.5).\textsuperscript{152} Collectively, benzodiazepines produce anxiolytic, amnestic, sedative, hypnotic, and anticonvulsant effects, but no analgesia.\textsuperscript{11} Class-wide adverse effects include cardiorespiratory depression, altered sensorium, and paradoxical excitatory reactions.\textsuperscript{152} Hemodynamic instability can occur with an etiology that is uncertain, but likely the result of blunting the stress response rather than direct vasodilation. Tolerance and withdrawal can develop with prolonged use and is addressed later.\textsuperscript{153}

The use of benzodiazepines has been scrutinized recently. They are associated with prolonged mechanical ventilation duration and ICU LOS
compared with nonbenzodiazepines (i.e., dexmedetomidine or propofol).\textsuperscript{11,154} These findings are probably the result of drug accumulation with long-term use and inappropriate sedation titration. In addition, the benzodiazepines have been inconsistently associated with the development of delirium.\textsuperscript{155-159} A causal relationship has yet to be established, and the association may stem from confounding of delirium assessments during sedation.\textsuperscript{160} This topic is further examined later. Despite these concerns, the benzodiazepines should continue to be viewed as first-line agents for acute agitation or alcohol withdrawal.

**Midazolam**

Midazolam is the most commonly used benzodiazepine in ICUs.\textsuperscript{102} It is about half as potent as lorazepam, and because it is highly lipophilic, it can accumulate in adipose tissue. Midazolam is metabolized by CYP3A4 to active metabolites, $\alpha$-hydroxymidazolam (60% potency of midazolam), and $\alpha$-hydroxymidazolam glucuronide (10% potency of midazolam), which are renally cleared.\textsuperscript{152} It works synergistically with propofol because of a CYP-mediated drug-drug interaction leading to increased midazolam availability or enhanced GABA receptor agonism.\textsuperscript{161,162} In general, it is most appropriate for acute agitation, inducing deep sedation for the treatment of refractory seizures or elevated ICP, as a premedication for procedures, or in the setting of hemodynamic instability that precludes the use of more readily titratable agents (propofol or dexmedetomidine).

| Table 7.5 | Pharmacologic Properties of Traditional Sedatives |
Continuous infusion requires mechanical ventilation.

PRN = as needed.

### Lorazepam

Lorazepam is the second most commonly used benzodiazepine in the ICU.\(^{102}\) It should be used as an intermittent injection because of its long half-life and propensity to accumulate in adipose tissue or in the setting of hepatic impairment.\(^{11}\) Lorazepam (high-performance liquid chromatography index relative to diazepam = 0.48) is less lipophilic than midazolam (high-performance liquid chromatography index relative to diazepam = 1.54), which results in a slower onset of action and slower egress from the CNS.\(^{11,129,163}\)

Propylene glycol toxicity, which can occur with high-dose lorazepam therapy, has hampered its use. Each 2-mg/mL vial contains 830 mg of

\(^{a}\)Continuous infusion requires mechanical ventilation.

propylene glycol. An infusion of 2 mg/hour to a patient weighing 70 kg would deliver 20 g of propylene glycol in 24 hours, which is about 11 times the allowable dose set forth by the World Health Organization. Propylene glycol toxicity manifests as metabolic acidosis (as a result of the production of pyruvate and lactic acid), renal impairment, and hyperosmolality. Because most centers cannot assay propylene glycol concentrations in a timely fashion, an osmolar gap of greater than 15 mOsm/kg can serve as a surrogate for accumulation of this toxin. Ultimately, lorazepam should be used judiciously as an intermittent injection to calm acutely agitated patients and to abort seizures.

Propofol

Propofol has recently become the most popular ICU sedative (Table 7.5). Its mechanism of action is uncertain and likely involves GABA, glycine, nicotinic, and muscarinic receptors. Stimulation of these receptors produces sedative, hypnotic, anxiolytic, amnestic, antiemetic, and anticonvulsant effects, but no analgesia. Propofol is readily titratable during short-term use, especially when titrated to light levels of sedation, because of rapid redistribution and high hepatic and extrahepatic clearance. However, it can accumulate in adipose tissue and slowly redistribute during prolonged infusions, resulting in a terminal half-life in excess of 24–30 hours.

Propofol is generally safe, but certain aspects of its administration can be problematic. Propofol induces dose-dependent respiratory depression and can cause hypotension because of systemic vasodilation. It is dissolved in a 10% lipid emulsion that contains egg lecithin and soybean oil, which can lead to allergic reactions, adds considerable calories (1.1 kcal/mL), and may lead to hypertriglyceridemia in as many as 18% of patients. Pancreatitis has also been described during propofol therapy. Although hypertriglyceridemia is a likely cause, reports of pancreatitis in the absence of hypertriglyceridemia suggest other mechanisms are at play. Serum triglycerides and lipase should be monitored regularly and infusions discontinued when triglyceride concentrations exceed 500
mg/dL. Rare reports of propofol-induced myoclonus exist.\textsuperscript{175} Of interest, propofol can turn urine green because of phenolic metabolites excreted in the urine.\textsuperscript{176}

Propofol-related infusion syndrome (PRIS) may occur in 1\%–10\% of patients, depending on the patient population studied.\textsuperscript{177,178} It has been associated with a mortality rate from 30\% to greater than 80\%.\textsuperscript{177} The pathophysiology is unknown, but it may occur because of mitochondrial toxicity.\textsuperscript{179} Propofol should be discontinued if unexpected metabolic acidosis, acute renal failure, rhabdomyolysis, transaminitis, hypotension, bradycardia, or Brugada-like coved ST-segments manifest.\textsuperscript{180-182} Doses should be capped at 80 mcg/kg/minute because of a possible link between propofol exposure and PRIS, but this has been challenged in a study that found 82\% of patients who developed PRIS were receiving doses of less than 83 mcg/kg/minute.\textsuperscript{177} Despite potentially profound adverse effects, propofol should be considered a first-line sedative in hemodynamically stable patients.

**Central $\alpha_2$-Receptor Agonists**

Centrally acting $\alpha_2$-receptor agonists (dexmedetomidine and clonidine) reduce sympathetic outflow to produce cooperative levels of sedation without respiratory depression (Table 7.5).\textsuperscript{183-185} Their primary site of action may be presynaptic neurons in the locus coeruleus, which regulates arousal, wakefulness, and sleep-wake cycles.\textsuperscript{186,187} Analgesic-sparing activity has been well described with $\alpha_2$-receptor agonists, which may be due to antinociceptive effects in the CNS and spinal cord.\textsuperscript{188,189} Their adverse effects include bradycardia, heart block, and hypotension.\textsuperscript{11} The $\alpha_2$-receptor agonists are rapidly becoming popular ICU sedatives.\textsuperscript{102,166}

**Dexmedetomidine**

Dexmedetomidine is the dextro enantiomer of medetomidine.\textsuperscript{25} Its use has steadily increased during the past 15 years.\textsuperscript{102} A $\alpha_2/\alpha_1$ selectivity ratio of 1620:1 is often cited, but medetomidine was used to establish
Loading doses should be avoided because of the risk of hypotension (\(\alpha_{2A}\)-receptor agonism) or hypertension (\(\alpha_{2B}\) or \(\alpha_1\)-receptor agonism).\(^{191}\) Dexmedetomidine is readily titratable despite a long half-life (2–2.5 hours), which may be prolonged in older adult patients and those with liver disease.\(^{25,192}\) Despite a relatively long half-life, the sedative effects of dexmedetomidine tend to wear off quickly after infusion discontinuation.\(^{193}\)

Dexmedetomidine offers many advantages over other sedatives. Maintenance of respiratory drive allows for administration to non-intubated patients and may facilitate mechanical ventilator weaning. Cooperative levels of sedation allow for self-reporting of pain, mobilization, and accurate delirium screening. Dexmedetomidine has typically been shown to reduce the incidence of delirium, duration of mechanical ventilation, and ICU LOS compared with benzodiazepines.\(^{11,154,194-196}\) It has also been used as an adjunctive agent in the management of alcohol withdrawal.\(^{197}\) Variability in response and drug acquisition cost are its most significant drawbacks.\(^{198}\) Drug acquisition cost may be offset by reduced ICU LOS, by shorter duration of ventilation, or with transition to enteral clonidine.\(^{199-201}\)

**Clonidine**

Clonidine is the prototypical \(\alpha_2\)-receptor agonist.\(^{202}\) It is much less selective for \(\alpha_2\)-receptors than medetomidine, with an \(\alpha_2/\alpha_1\) selectivity ratio of 220:1.\(^{190}\) Clonidine is highly lipophilic and produces dose-dependent sedation within 1–2 hours after an enteral dose, which coincides with peak plasma concentrations.\(^{203-205}\) Clonidine is routinely used internationally as an intravenous sedative.\(^{202,206-209}\) Enteral clonidine represents an emerging stand-alone sedative or alternative to dexmedetomidine in the United States.

Until recently, data supporting the use of enteral clonidine as an ICU sedative were limited to case reports and pediatric studies.\(^{210-212}\) A recent single-center study showed that transitioning from dexmedetomidine to enteral clonidine (0.2–0.5 mg every 6–8 hours)
may be a safe, effective, and less-costly way of providing $\alpha_2$-receptor agonist therapy.\textsuperscript{200} Similarly, a randomized trial found that enteral clonidine (0.1–0.2 mg three times daily) reduced morphine and midazolam requirements.\textsuperscript{213} Withdrawal, which may occur in 13%–86% of patients receiving it for hypertension, is usually mild (e.g., palpitations, insomnia, or tremor) and can be avoided by tapering the dose on discontinuation.\textsuperscript{214-216} Clonidine patches should be avoided because peak and steady-state concentrations are not reached until 4 days after the transdermal system is applied.\textsuperscript{205} Ultimately, more robust data on clonidine as an ICU sedative are needed.

**Alternative Sedatives**

**Valproic Acid**

Valproic acid is a simple, branched-chain carboxylic acid that was first isolated in 1882 (Table 7.6).\textsuperscript{217} Mechanistically, it blocks voltage-dependent sodium and calcium channels, increases GABA synthesis, potentiates GABA release, blocks GABA degradation, and attenuates the activation of NMDA receptors.\textsuperscript{218} These actions culminate in anticonvulsant and mood-stabilizing effects. Recently, valproic acid has been used to treat alcohol withdrawal, agitation in dementia, and schizophrenia.\textsuperscript{219-221}

Data describing valproic acid’s safety and efficacy in critically ill patients are limited to two abstracts and a case series.\textsuperscript{222-224} A loading dose of 30 mg/kg followed by 30 mg/kg/day may be appropriate according to bipolar disorder guidelines and anecdotal evidence.\textsuperscript{225} Serum concentrations can be monitored and maintained between 50 mcg/mL and 125 mcg/mL because exposure may play a role in its efficacy.\textsuperscript{226}

Patients receiving valproic acid should be monitored for several adverse effects. Ammonia concentrations should be obtained to monitor for hyperammonemia, which is because of valproic acid’s interference with the urea cycle.\textsuperscript{227} Levocarnitine therapy should be reserved for severe situations because the serum ammonia
concentration will often return to normal after discontinuation.\textsuperscript{228} Thrombocytopenia can occur and may be immune mediated in the acute setting or because of marrow suppression in the chronic setting.\textsuperscript{229,230} Hepatotoxicity and pancreatitis are well described and require periodic liver function and serum lipase monitoring.\textsuperscript{231,232} Valproic acid should be discontinued if a rash develops because of the risk of Stevens-Johnson syndrome.

Drug-drug interactions should also be monitored for during valproic acid therapy. Carbapenem antibiotics reduce valproic acid serum concentrations by more than 50\%.\textsuperscript{233,234} Proposed mechanisms include repression of valproic acid absorption from the intestinal lumen, reduced enterohepatic recirculation because of decreased $\beta$-glucuronidase activity, increased hepatic glucuronidation because of increases in uridine diphosphate glucuronic acid concentrations, and increased distribution of valproic acid into red blood cells.\textsuperscript{234} In addition, valproic acid is a CYP2C9 inhibitor, which may reduce the metabolism of CYP2C9 substrates (e.g., phenobarbital, phenytoin, or carbamazepine). However, valproic acid’s metabolism can be increased by CYP2C9 inducers (e.g., phenobarbital, phenytoin, carbamazepine, or rifampin) or decreased by CYP2C19 inhibitors (e.g., felbamate or topiramate).\textsuperscript{235}

jPanzer O, Moitra V, Sladen RN. Pharmacology of sedative-analgesic agents:
Phenobarbital

Phenobarbital is a barbiturate that was first developed in 1911 (Table 7.6).236 The barbiturates prolong GABA channel opening, which increases chloride ion influx and hyperpolarizes neuronal membranes.237 This action results in anticonvulsant, anesthetic, anxiolytic, and sedating effects. Phenobarbital use is limited because of its long half-life (70 to 145 hours), which results in poor titratability.236 Interest in phenobarbital has increased because it does not require mechanical ventilation for administration and can be given enterally.

Phenobarbital is predominantly used to treat alcohol withdrawal and refractory seizures.236,238 Only one case series has described its safety and tolerability for ICU sedation.239 In that study, an intravenous loading dose of 7.5 mg/kg was followed by a maintenance regimen of 1–2 mg/kg intravenously divided twice daily with 65- to 130-mg rescue doses as needed. Phenobarbital was well tolerated and was not associated with hemodynamic derangements.

Other than sedation, adverse effects associated with phenobarbital are relatively uncommon. Patients receiving intravenous loading doses should be monitored for cardiorespiratory depression. Clinically significant drug interactions may occur during phenobarbital therapy because it is a potent inducer of CYP3A4 and the CYP2C subfamily.235 Serum concentration monitoring is not necessary unless toxicity is suspected. Phenobarbital can be considered in severe agitation or...
alcohol withdrawal, but more data are needed to define its role in the ICU.

**Ketamine**

Ketamine is a dissociative anesthetic and phencyclidine derivative that gained popularity on the battlefield during the Vietnam War (Table 7.6). Its mechanism of action includes NMDA receptor antagonism and mu and kappa opioid receptor agonism. These actions produce dissociative, sedative, analgesic, and amnestic effects. Interest in ketamine to provide comfort in the ICU has increased because it does not depress cardiorespiratory function.

Few studies have described the use of ketamine as a continuous infusion to manage agitation in the ICU. Because of this and unfamiliarity with its use, it is typically reserved for severe agitation or intractable pain. Of interest, ketamine has been shown to attenuate delirium after cardiac surgery. In addition, it has been used to manage alcohol withdrawal.

Patients receiving ketamine should be monitored for a hyperadrenergic state, exacerbation of coronary ischemia, psychiatric disturbances, and emergence phenomena (confusion, nightmares, or hallucinations). Although earlier data suggested it increases ICP, recent studies have refuted this. Until more robust data are available, ketamine should be reserved for select patients who do not respond to more traditional agents.

**Antipsychotics**

Antipsychotics antagonize dopamine, serotonin, histamine, α-adrenergic, and muscarinic receptors, resulting in mood-stabilizing effects. They are characterized as typical (chlorpromazine, perphenazine, prochlorperazine, and haloperidol) or atypical (aripiprazole, clozapine, olanzapine, quetiapine, and risperidone). Each antipsychotic has a unique affinity for the receptors it interacts with, which leads to varying degrees of response. Most studies describe antipsychotic use for hyperactive delirium. Data supporting their use
for primary agitation have not been developed. Nonetheless, they are commonly used.\textsuperscript{249-252}

Haloperidol is the most commonly used antipsychotic because of the availability of a parenteral formulation, although this route of administration has not been approved by the U.S. Food and Drug Administration. Intermittent boluses of 0.5–10 mg intravenously as needed are reasonable. Quetiapine (12.5–100 mg given every 6–12 hours) and olanzapine (2.5–30 mg/day) may also be used.\textsuperscript{253,254} Patients receiving antipsychotics should be closely monitored for extrapyramidal symptoms (akathisia, parkinsonism, or dystonias), QTc interval prolongation, and neuroleptic malignant syndrome.\textsuperscript{164,255,256} In addition, these agents can lower the seizure threshold.\textsuperscript{257} More information on the antipsychotics can be found in the Delirium chapter.

**Volatile Anesthetics**

The introduction of an anesthetic-conserving device to reduce atmospheric pollution has led to renewed interest in volatile anesthetics (isoflurane, sevoflurane, and desflurane) as ICU sedatives.\textsuperscript{258} These agents may interfere with GABA activity or interact with cell membrane lipids, proteins, or ion channels. These mechanisms result in rapid loss of consciousness, immobility, analgesia, anterograde amnesia, and respiratory depression.\textsuperscript{25,259} Volatile anesthetics are predominantly eliminated by the lungs, but small amounts are cleared hepatically by CYP2E1.\textsuperscript{260} Adverse effects include hemodynamic instability, malignant hyperthermia, and renal or hepatic toxicity.\textsuperscript{261} In addition, sevoflurane-induced sedation in patients with stroke or subarachnoid hemorrhage has been associated with transient elevations in ICP.\textsuperscript{262} Volatile anesthetics have been included in international ICU comfort guidelines because of their titratability, tolerability, favorable pharmacokinetic profiles, and potential post-conditioning effects.\textsuperscript{209,263}

Data describing the safety and efficacy of volatile anesthetics are limited. Isoflurane has been the most studied agent, followed by sevoflurane and desflurane. Most investigations have shown that they shorten awakening time after sedative discontinuation compared with
traditional agents (midazolam or propofol); however, results are conflicting. They may also shorten time to extubation after sedation discontinuation and be associated with better survival and psychological outcomes. Interpreting these studies is difficult because of variations in the patients studied, duration of sedation, anesthetic used, control group treatment, outcomes reported, and use of validated sedation scales. Concerns about the use of these agents include the short- and long-term impact of atmospheric pollution on caregivers, use by non-anesthesiologists, costs, and operational issues. Routine use should be reserved until these shortcomings are addressed.

Hydroxyzine

Hydroxyzine is a first-generation antihistamine that antagonizes H₁ receptors. It also has anticholinergic, anti-serotonergic, antiemetic, and gastric antisecretory properties. Hydroxyzine has been used for several decades for generalized anxiety and as an anesthesia premedication. It has been evaluated as an enteral ICU sedative in adults at a dose 6–12 mg/kg/day in divided doses. More recent data suggest that doses should not exceed 100 mg/day in adults or 50 mg/day in older adult patients because of the risk of QT interval prolongation and cardiac arrhythmias. In addition, hydroxyzine should be avoided in patients with acquired or congenital QT interval prolongation, electrolyte abnormalities (hypokalemia or hypomagnesemia), family history of sudden cardiac death, significant bradycardia, or concomitant use of drugs known to prolong the QT interval.

IATROGENIC WITHDRAWAL FROM SEDATION

Caregivers should closely monitor patients for signs and symptoms of withdrawal after extended exposure to sedatives. Withdrawal may occur in 32% of patients who received at least 7 days of sedation. Risk factors may include higher daily and peak exposures and abrupt
weaning of these agents.\textsuperscript{278,279} Acute opioid withdrawal may occur because of hyperactivity within the nociceptive system, which is supported by studies that have shown β-endorphins and met-enkephalins are elevated during withdrawal.\textsuperscript{280} Symptoms are often the opposite of the drug’s pharmacologic effect and include agitation, tachycardia, hypertension, tachypnea, insomnia, delirium, nausea, diarrhea, diaphoresis, and fever.\textsuperscript{281} Diagnosing iatrogenic withdrawal can be accomplished by replenishing the drug in question and observing the patient’s response.

To avoid precipitating withdrawal, slow tapering of sedation is encouraged. Reducing infusion rates by 25\%–50\% per day is a reasonable approach. Methadone or other longer-acting enteral opioids (e.g., hydromorphone or oxycodone) can be used to facilitate the discontinuation of opioid infusions.\textsuperscript{149,150} Longer-acting benzodiazepines like clonazepam can be used to taper off benzodiazepine infusions. Although withdrawal from dexmedetomidine rarely occurs in routine practice, clonidine can be used to transition off dexmedetomidine.\textsuperscript{200,282} Pharmacists are well situated to identify patients at risk of withdrawal and to develop sedation-tapering strategies.

\section*{TRANSITIONS OF CARE AND SEDATION}

Pharmacists are in an excellent position to improve transitions of care. It is not uncommon for patients to be transferred from the ICU or discharged home on a new psychoactive medication. Confounding the situation is the fact that 36\% of medications are used off-label in the ICU, which can create confusion during de-escalation of care.\textsuperscript{283} One study found that 47\% of patients prescribed an atypical antipsychotic in the ICU have them continued on ICU discharge.\textsuperscript{284} In a recent systematic review of ICU discharge literature, only 2\% of studies focused on medication reconciliation.\textsuperscript{285} Strategies to improve transitions of care are desperately needed and should be a focus of future research efforts.
SEDATION CONFOUNDING OF DELIRIUM ASSESSMENTS

The introduction of valid and reliable delirium screening tools in 2001 represented a monumental advancement in ICU care. These tools allowed for a more rigorous assessment of risk factors for ICU delirium and significant advances in our understanding of this complex process. Preexisting dementia, hypertension, alcoholism, and coma have consistently been identified as risk factors, whereas an association between sedative use and ICU delirium has been less clear.11 The benzodiazepines have been the most implicated agents, but the issue may be broader than a single agent or drug class.155-159

Level of consciousness is a central component of both the confusion assessment method for the intensive care unit (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC).286,287 Sedatives, from any drug class, have the ability to interfere with level of consciousness and therefore delirium assessments. One study has shown that the frequency of positive CAM-ICU assessments increased by 20% if the RASS score went from -2 to -3.288 Although the original studies of the ICDSC did not address the potential for sedatives to confound assessments, subsequent studies have suggested that components of the ICDSC that are influenced by sedation should not be assessed in the presence of sedatives.158 No such clarification has been made regarding the CAM-ICU.

Recent data have begun to elucidate the differences between persistent and rapidly reversible sedation-related delirium.288,289 In the study by Patel et al., CAM-ICU assessments were completed before and after sedation interruption, and patients were classified as never delirious, as persistently delirious (positive CAM-ICU scores 2 hours after sedation discontinuation), or as having rapidly reversible sedation-related delirium (positive CAM-ICU scores before sedation interruption but negative scores after). Patients with rapidly reversible sedation-related delirium had long-term outcomes similar to those who were never delirious. Of importance, only 54% of patients were exposed to midazolam in that trial for a median duration of 1 hour, whereas more
than 95% received propofol and fentanyl. In the study by Haenggi et al., just 20% of patients received continuously infused benzodiazepines. These data suggest that rapidly reversible sedation-related delirium can occur with any sedative and that its impact on outcomes is unclear. Accordingly, the 2013 SCCM PAD guidelines suggest that delirium assessments be completed when patients are wakeful (i.e., SAS 3 to 4 or RASS –2 to 0 or ability to follow simple commands).11

SEDATION STRATEGIES

One of the most important discoveries in ICU sedation during the past 2 decades has been that the method by which sedatives and analgesics are administered is just as important as the drugs themselves. Titration of sedatives to comfort and wakefulness allows patients to participate in their care. It also allows a more accurate rendering of analgesic need and the presence of delirium. Beyond this, light sedation may affect long-term outcomes by facilitating early mobilization and its associated beneficial effect on functional outcomes and the formation of factual memories, which may limit the risk of posttraumatic stress disorder.290-293

Deep sedation, by contrast, may be associated with delayed liberation for mechanical ventilation; higher inhospital, 180-day, and 2-year follow-up mortality; and a greater need for tracheostomy.294-298 In addition, deep sedation has been associated with lack of ICU recall and delusional memories, which may increase the risk of posttraumatic stress disorder.299-301 Deep sedation may be appropriate in certain situations (e.g., neuromuscular blockade, ventilator dyssynchrony, status epilepticus, open abdomen, or elevated ICP). Despite the availability of a large amount of consistent data suggesting that light sedation confers outcomes benefits, 40%–50% of patients remain oversedated, and 32% of patients continue to be sedated to the point of coma.250,251

Protocolized Sedation
A protocolized approach to comfort is endorsed in the 2013 SCCM PAD guidelines. Although daily sedation interruption is often a component of a sedation protocol, it will be discussed separately in this chapter. Protocols emphasize the identification of underlying etiologies of discomfort, selection of a patient-specific sedation goal, liberal treatment of pain, and the choice of sedative or analgesic depending on sedation goal and end-organ function. Protocols are often managed autonomously by bedside nurses. The benefits of a sedation protocol largely stem from thoughtful titration of sedation. Despite clear advantages, about 30% of ICUs do not use sedation protocols.302

Until the late 1990s, most studies on ICU comfort focused on comparing one sedative with another. A landmark trial changed that by evaluating a nurse-driven sedation protocol.303 The protocol encouraged nurses to identify and address possible etiologies for agitation, treat pain with intermittent boluses of opioids, and treat agitation with intermittent boluses of benzodiazepines. Continuous infusions were reserved for persistent agitation. The nurse-driven protocol shortened the duration of continuously infused sedation, mechanical ventilation, ICU and hospital LOS, and tracheostomy rate compared with the standard of care (i.e., physician order only). Those findings ignited a wave of studies that evaluated sedation protocols.

Most studies have shown that a protocolized approach to comfort reduces duration of mechanical ventilation.53,303-312 This is usually associated with a shorter hospital and ICU LOS.53,303-305,307-311 These benefits are probably because of reduced exposure to sedatives and the avoidance of coma.53,303-305,307-313 No increases in self-extubation, physical restraints, nurse workload, or psychological distress have been noted in these studies.53,304-307,310,314,315 Although most trials have shown that protocolized sedation improves outcomes, a select few have questioned its benefits.316-318 Most conflicting data have their genesis in ICU health care models that use 1:1 nurse/patient ratios, closed units, nurse ventilator management, and shorter-acting sedatives like propofol. Nonetheless, a recent meta-analysis found that protocolized sedation improves outcomes compared with usual care.319

The ideal protocol should be developed by a multi-disciplinary team.
First, it should mandate systematic assessments of sedation and agitation at least four times per nursing shift. Second, it should encourage the identification and correction of the underlying etiology. Third, it should emphasize the establishment of a patient-specific sedation goal. In the absence of an indication for deep sedation, targeting wakefulness is encouraged. Fourth, it should stress routine pain assessment and treatment. Fifth, it should advocate for intermittent boluses of sedatives and analgesics. If it is ineffective, continuous infusions of short-acting agents (dexmedetomidine or propofol) should be encouraged. Titration and taper instructions should be present. Finally, it should incorporate spontaneous breathing trials and delirium assessments when patients are wakeful (i.e., SAS 3 to 4 or RASS –2 to 0 or ability to follow simple commands).

**Sedation Interruption**

Daily sedation interruption involves the discontinuation of continuously infused sedatives until patients are wakeful. Interruption allows for more productive neurological examinations, spontaneous breathing trials, delirium screening, mobilization attempts, and self-reporting of pain. Indications to forego interruption include active seizures, alcohol withdrawal, neuromuscular blockade, hemo-dynamic instability, elevated ICP greater than 20 mm Hg, extracorporeal membrane oxygenation, myocardial ischemia in the past 24 hours, and dangerous agitation.\textsuperscript{290,320,321} Interruption in patients with neurological injury should be done with caution because dangerous elevations of ICP, cerebral perfusion pressure, and catecholamine concentrations; hemodynamic instability; and reductions in brain tissue oxygen tension may occur.\textsuperscript{58,322,323}

Daily sedation interruption was evaluated in a sentinel trial in 2000.\textsuperscript{324} It reduced the duration of mechanical ventilation, ICU LOS, sedatives and analgesics administered, and need for diagnostic tests to evaluate neurological status. Conversely, it increased the number of days that patients were wakeful and improved discharge disposition. A subsequent analysis found that ICU complications (e.g., ventilator-
associated pneumonia, gastrointestinal bleeding, or bacteremia) were reduced by 50%. Initial concerns about psychological distress and cardiovascular compromise were later thwarted. Although more recent trials and a meta-analysis have questioned the utility of sedation interruption, its benefits likely outweigh the risks.

Only one study has compared protocolized sedation with protocolized sedation with a daily interruption. The protocol maximized the use of opioids, minimized benzodiazepines, and targeted light levels of sedation (SAS 3 or 4 or RASS -3 to 0). Of interest, clinical outcomes were similar between groups. These findings could have been because of higher benzodiazepine and opioid use in the intervention group, the low rate of sedation interruption (72%), not pairing spontaneous breathing trials with sedation interruption, or the fact that sedation was titrated by bedside versus research nurses. The 2013 SCCM PAD guidelines recommend that either daily sedation interruption or a protocolized approach to comfort be used.

Interruption of sedation has rapidly become a component of ICU care bundles, which incorporate evidence-based, multicomponent, and multidisciplinary strategies into everyday practice. Pairing sedation interruption with spontaneous breathing trials has been shown to increase ventilator-free days and reduce ICU and hospital LOS, 1-year mortality, days with coma, and benzodiazepine doses. Long-term cognitive and psychological outcomes were similar between groups at 12 months. Combining sedation interruption with spontaneous breathing trials and early mobilization increases ventilator-free days and mobilization while decreasing delirium, hospital mortality, and benzodiazepine use. Unfortunately, daily sedation interruption is at best used in 78% of eligible patients because of concerns about medical device removal, respiratory compromise, patient discomfort, and lack of adequate patient care resources. Education and quality improvement initiatives can address this.

**SUMMARY AND FUTURE DIRECTIONS**

Despite more attention than ever before, agitation is still common in
critically ill patients. It is often because of a combination of patient-related, illness-related, and environmental factors. Discomfort in the ICU can be distressful for patients, families, and caregivers. In addition, it is closely linked to negative clinical outcomes and maladaptive physiologic responses. Routine assessment of comfort with subjective sedation scales or objective measures is imperative. Nonpharmacologic interventions should used in all ICU patients with the understanding that pharmacologic therapy will often be necessary. Sedation protocols should guide the administration of sedatives and analgesics and should focus on treating pain first and targeting wakefulness, when clinically appropriate.

Several gaps remain in how best to provide comfort in the ICU. The role of pharmacists as sedation stewards needs to be further evaluated. Strategies to reduce inappropriate continuation of psychoactive medications initiated in the ICU during transitions of care need to be developed. Sedation strategies in non-intubated patients or those with neurological injuries, end-organ dysfunction, or hemodynamic instability need to be better established. The short- and long-term impact of sedation-related delirium is only beginning to be elucidated. In addition, more robust data are needed in respect to alternative sedatives. Although these questions and many others remain unanswered, a systematic and multidisciplinary approach to ICU comfort can improve outcomes during a hospitalization and beyond.

Chapter 8  Delirium in Critically Ill Adults

John W. Devlin, Pharm.D., FCCP, FCCM

LEARNING OBJECTIVES
1. Describe the outcomes of delirium in critically ill adults.
2. Recognize the importance of routine delirium screening in the intensive care unit (ICU) using the CAM-ICU (Confusion Assessment Method for the Intensive Care Unit) or the ICDSC (Intensive Care Delirium Screening Checklist).
3. Identify modifiable risk factors for delirium in critically ill adults.
4. Apply nonpharmacologic strategies to reduce the burden of delirium in critically ill adults.
5. Understand the current limited role of medication when treating delirium in the ICU.

ABBREVIATIONS IN THIS CHAPTER

ABCDEF  Assessment, prevention, and management of pain, Both spontaneous awakening trials and spontaneous breathing trials, Choice of analgesia and sedation, Delirium assessment, prevention, and management, Early mobility and exercise, and Family engagement and empowerment

CAM-  Confusion Assessment Method for the Intensive Care
INTRODUCTION

Delirium is often encountered in the intensive care unit (ICU) and is associated with significant adverse outcomes. The increasingly recognized consequences of ICU delirium should enhance efforts to improve recognition and management of this serious sequelae of critical illness. We aim to review the recent literature on ICU delirium, including risk factors, detection, management, and the long-term impact of this disease.

DESCRIPTION OF DELIRIUM

Delirium is a syndrome characterized by the acute onset of cerebral dysfunction with a change or fluctuation in baseline mental status, inattention, and either disorganized thinking or an altered level of consciousness. The cardinal features of delirium are (1) a disturbed level of consciousness (i.e., a reduced clarity of awareness of the environment), with a reduced ability to focus, sustain, or shift attention; and (2) either a change in cognition (i.e., memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance (i.e., hallucinations, delusions).

Although the recent fifth edition of the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association now operationalizes “consciousness” as “changes in attention,” this minor change does not influence the validity of instruments developed
for delirium recognition in the ICU, given that level of arousal, a key part of attention, corresponds directly with level of consciousness, and all patients must have an adequate level of arousal before the presence of inattention can be evaluated.\(^2\)

Other symptoms commonly associated with delirium include sleep disturbances, abnormal psychomotor activity, hallucinations/delusions, and emotional disturbances (i.e., fear, anxiety, anger, depression, apathy, and euphoria).\(^3\) These symptoms are often those that are of most concern to patients, family members, and caregivers and thus often require treatment. Patients with delirium may be agitated (hyperactive delirium), calm, or lethargic (hypoactive delirium), or they may fluctuate between the two subtypes (mixed).\(^4\) Among patients with delirium, 75% have delirium that is either hypoactive or mixed. Patients with only some of the characteristics of delirium have subsyndromal delirium, a condition that may result in outcomes almost as bad as those with delirium.\(^5\)

Although epidemiologic studies from more than a decade ago reported delirium to occur in up to 80% of mechanically ventilated, critically ill adults, more recent investigations of ICU patients who are less likely to be deeply sedated and more likely to have been mobilized report a delirium incidence rate closer to 40%.\(^6,7\) The likelihood that delirium will occur in any ICU patient is dependent on the patient’s baseline risk of delirium and the number of delirium-precipitating causes the patient is exposed to during the ICU stay.\(^8\) Critically ill medical patients have a higher incidence of delirium than do surgical patients, particularly patients undergoing cardiac surgery. Up to 30% of ICU patients are admitted to the ICU with delirium.\(^6,7\)

During their ICU stay, critically ill patients may develop a subcategory of delirium related to either drug withdrawal or alcohol withdrawal, which usually manifests as a hyperactive type of delirium. The pathophysiology, diagnosis, and treatment of delirium related to drug and alcohol withdrawal is distinct from delirium related to other causes and thus will not be reviewed in this chapter.\(^9\)
Delirium, as a manifestation of acute brain dysfunction, is an important independent predictor of negative clinical outcomes in the ICU, including self-extubation, duration of mechanical ventilation, length of ICU stay, and ICU mortality. Delirium increases both hospital and longer-term (e.g., 6 months) mortality. The trajectory of a patient’s severity of illness during the ICU admission influences the relationship between delirium occurrence and mortality. Given that the number of ICU days spent with delirium is associated with both 6- and 12- month mortality, optimizing the use of strategies shown to reduce the number of ICU days spent with delirium is an important goal of therapy.

At hospital discharge, patients who developed delirium in the ICU are more likely to transition to a skilled nursing facility (e.g., nursing home) than to a rehabilitation facility or home. Delirium may lead to long-term cognitive impairment that is not unlike that seen in patients with dementia or a traumatic brain injury. These cognitive deficits often persist for weeks or months (or never resolve at all) and often delay a return to work and the ability to resume pre-critical illness activities and function. Patients who experience ICU delirium have a greater incidence of depression and often experience prolonged sleep abnormalities. This burden of delirium can have profound effects on spouses and family members, particularly if they are required to assume a caregiver role on a persistent basis. Given that the effects of delirium often persist long after ICU discharge, delirium is now recognized as a major public health problem that costs the United States up to $16 billion each year.

PATHOPHYSIOLOGY OF DELIRIUM IN THE ICU

Although the study of delirium in critically ill patients has expanded tremendously during the past 15 years, the underlying pathophysiology of delirium in this population remains poorly understood. Although several different metabolic pathways have been postulated to cause delirium, including inflammation, neurotransmitter dysfunction, ischemia, glucose dysregulation, disruption of the hypothalamic-pituitary axis, and tryptophan metabolism, our understanding of how these various
mechanisms interact to cause delirium state remains limited (Figure 8.1). It should be emphasized that this is a complex area of research, given that delirium likely occurs through a complex interplay of different systems and mechanisms and that critical illness itself is a dynamic, ever-changing process. A valid animal model for delirium has yet to be developed. Finally, neither imaging techniques nor bio-markers have been shown as valid methods to either predict or identify delirium in the ICU; thus, all mechanistic-focused delirium studies in this setting still rely on a diagnosis of delirium that is based on a symptom-based assessment at the patient bedside.

RECOGNITION OF DELIRIUM IN THE ICU

Given the multifactorial and fluctuating nature of delirium, a cursory “one-time only” evaluation of delirium at the ICU bedside, without the use of a validated screening tool, is often ineffectual and is thus a poor strategy to identify delirium in critically ill adults. Delirium is challenging to recognize in the ICU setting: most patients are intubated and cannot verbally communicate, the use of medications that reduce level of consciousness is prevalent, hypoactive delirium is common, and patients may be too unstable to participate in lengthy assessments. The ability to accurately evaluate for delirium is a key component when developing ICU strategies focused on reducing reversible causes for delirium and promoting the regular interprofessional discussion of the cognitive status of patients.

The ideal delirium screening tool combines high sensitivity (i.e., will be positive when delirium is present) and high specificity (i.e., will be negative when delirium is not present). Among the ICU delirium screening tools developed, the Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC) have the greatest psycho-metric strength. A comprehensive discussion of the psychometric properties of the CAM-ICU and ICDSC is beyond the scope of this chapter. Nevertheless, two recent meta-analyses highlight the robust data that support the use of
the CAM-ICU or the ICDSC in clinical practice.\textsuperscript{18,19}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure8.1.png}
\caption{Postulated mechanisms for delirium.}
\textsuperscript{GABA} = \textit{\textgamma}-aminobutyric acid.
\end{figure}

**The Confusion Assessment Method for the ICU**

The CAM-ICU is derived from the confusion assessment method and accounts for the nonverbal nature of most ICU patients by substituting the Attention Screening Exam for the Mini-Mental State Examination.\textsuperscript{2} This instrument evaluates the four key diagnostic features of delirium: (1) acute change or fluctuation in mental status from baseline, (2) inattention, (3) altered level of consciousness, and (4) disorganized thinking (Figure 8.2).\textsuperscript{16}

Feature 1 uses clinical information to assess the patient’s mental
status and is positive if the patient has a change in mental status from his or her prehospital baseline or has a fluctuation in mental status during the preceding 24 hours. Feature 2 asks the patient to complete a test of attention (e.g., asking the patient to squeeze the examiner’s hand every time the patient hears the letter “A” as the examiner spells out S-A-V-E-A-H-A-A-R-T). Feature 3 evaluates level of consciousness with the use of a sedation scale (e.g., Richmond Agitation-Sedation Scale [RASS]) and is positive if the patient’s level of consciousness is anything but alert and calm. Finally, feature 8.4 evaluates for disorganized thinking by asking the patient to perform a multistep task (e.g., holding up two fingers and then adding a third) and by answering four “yes/no” questions (e.g., Do fish live in the sea?). The CAM-ICU is considered positive if features 1 and 2 and either feature 3 or feature 4 is present.

Of note, patients who are deeply sedated (RASS of -4 or less) cannot be evaluated with the CAM-ICU until they are more awake. Although the RASS is the standard sedation scale used in conjunction with the CAM-ICU, other validated sedation scales like the sedation-agitation scale (SAS) can be used. Patients receiving continuous sedation should be evaluated for delirium with the CAM-ICU after a spontaneous awakening trial (SAT) given that delirium that is recognized before the SAT is likely to be rapidly reversible and not clinically significant. It is recommended to perform CAM-ICU screening several times per day (at a minimum twice) given the fluctuating nature of delirium. Additional assessments are recommended when changes in mental status occur.

The Intensive Care Delirium Screening Checklist

The Intensive Care Delirium Screening Checklist (ICDSC) is an eight-item instrument based on criteria of the fourth edition of Diagnostic and Statistical Manual of Mental Disorders and other features of delirium that evaluates eight different delirium domains (Table 8.1). The ICDSC was developed to provide ICU providers with an easy-to-use bedside screening tool that circumvents the communication limitations
of ICU patients, incorporates data that are gathered during routine patient care and can be completed quickly by the patients’ nurse, physician, or pharmacist. Patients who are not heavily sedated (i.e., RASS of -4 or less or SAS of 2 or less) are evaluated for domains 1–4 using a focused bedside assessment, for domains 5 and 6 over the course of the shift and domains 7 and 8 over the current and previous shift (i.e., during the prior 24 hours). At the end of each nursing shift, 1 point is given for each domain that is present, with a score of 4 or higher denoting the presence of delirium.

Although the ICDSC evaluates more symptoms of delirium than the CAM-ICU, the symptoms that each share in common (i.e., inattention, disorientation and agitation) are the delirium symptoms that are most commonly detected during ICDSC use and that have the best ability to discriminate between patients with delirium and those without.\textsuperscript{3,14,17} The ICDSC can identify patients with subsyndromal delirium (i.e., an ICDSC score of 1–3). Emerging data also suggest that the CAM-ICU can be used to detect subsyndromal delirium.\textsuperscript{5}

**Implementing and Sustaining Delirium Screening Efforts**

Because of the many limitations associated with use of a subjective approach, new consensus guidelines from the Society of Critical Care Medicine advocate that critically ill patients should be routinely screened for delirium using either the CAM-ICU or the ICDSC.\textsuperscript{9} More information about each tool may be found at [www.icudelirium.org](http://www.icudelirium.org). Many studies have shown that large-score implementation of a delirium screening tool in the ICU is both feasible and sustainable.\textsuperscript{14} Education regarding delirium assessment should be provided both didactically and at the bedside to all members of the ICU team and on a regular basis.\textsuperscript{14} The results of delirium screening efforts should be presented during morning report and/or bedside rounds.\textsuperscript{21} All ICU clinicians, including pharmacists and physicians, should be trained to screen for delirium in their patients. Routine delirium screening plays an integral role in the “ABCDEF” approach to managing sedation, delirium, early
mobilization, and mechanical ventilation. The ABCDEF is a standard bundle of ICU measures that includes routine Assessment for and management of pain, Both SATs and spontaneous breathing trials (SBTs), attention to the Choice of sedation and analgesia, Delirium monitoring and management, Early mobility, and Family engagement.

Figure 8.2 Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) flowsheet.

Table 8.1 The Intensive Care Delirium Screening Checklist

1. Altered level of consciousness Choose ONE from A–E.
Note: May need to reassess patient if current or recent administration of sedation therapy

| A. Exaggerated response to normal stimulation | Riker/SAS = 5, 6, or 7 | Score 1 point |
| B. Normal wakefulness | Riker/SAS = 4 | Score 0 point |
| C. Response to mild or moderate stimulation (follows commands) | Riker/SAS = 3 | Score 1 point |
| D. Response only to intense and repeated stimulation (e.g., loud voice and pain) | Riker/SAS = 2 | Stop assessment |
| E. No response | Riker/SAS = 1 | Stop assessment |

2. **Inattention** Score 1 point for any of the following abnormalities:
   - A. Difficulty in following commands OR
   - B. Easily distracted by external stimuli OR
   - C. Difficulty in shifting focus

   **Does the patient follow you with his/her eyes?**

3. **Disorientation** Score 1 point for any one obvious abnormality:
   - A. Mistake in time, place, or person

   **Does the patient recognize ICU caregivers who have cared for him/her and not recognize those who have not? What kind of place are you in? (list examples)**

4. **Hallucinations or Delusions** Score 1 point for either:
   - A. Equivocal evidence of hallucinations or a behavior caused by hallucinations
     *(Hallucination = perception of something that is not there with NO stimulus) OR*
   - B. Delusions or gross impairment of reality testing
     *(Delusion = false belief that is fixed/unchanging)*

   Any hallucinations now or during past 24 hr? Are you afraid of the people or things around you? [fear that is inappropriate to the clinical situation]

5. **Psychomotor Agitation or Retardation** Score 1 point for either:
   - A. Hyperactivity requiring the use of additional sedative drugs or restraints in order to control potential danger (e.g., pulling out IV lines or hitting staff) OR
**RISK FACTORS FOR DELIRIUM**

During the past decade, a vast amount of research has focused on better understanding those aspects of ICU delirium that are predictable, preventable, detectable, and treatable. Any critically ill patient’s risk of delirium depends on a complex interplay between predisposing and precipitating risk factors. Given the current paucity of effective treatment options for delirium in the ICU, clinicians should
focus their efforts on preventing delirium as soon as the patient is admitted to the ICU given that many risk factors for delirium in this setting are potentially modifiable.\textsuperscript{9,21} Early recognition of these potentially reversible risk factors should constitute the foundation of all ICU delirium prevention programs.

Although the number of published ICU delirium risk factor papers has expanded considerably during the past few years, the methodological rigor of many of these studies is poor, the patient case-mix is variable, and both the method and the intensity of delirium evaluation are less than ideal.\textsuperscript{8} Although cohort studies evaluate association, only randomized controlled studies define causality.\textsuperscript{23} A recent ICU delirium risk factor systematic review is instructive.\textsuperscript{8} Although almost more than 1,000 studies were initially identified, only 25 high-quality studies, each incorporating appropriate multivariate modeling, were able to be included. Among the 90 potential ICU risk factors for delirium evaluated in these studies, only 18 factors were deemed to have a level of evidence that was adequate to define them as risk factors. Strong risk factors included age, a history of dementia, the need for pre-ICU emergency surgery or trauma, a greater severity of illness (as defined by the admission APACHE II [Acute Physiology and Chronic Health Evaluation II] score), need for mechanical ventilation, presence of sepsis, metabolic acidosis, or iatrogenic coma and benzodiazepine use. Risk factors classified as moderate were alcohol consumption, hyper-tension, moderate cognitive impairment, admission with infection or respiratory insufficiency, medical admission and opioid use. One recent evaluation of the SLEAP randomized study found the following modifiable antecedent factors to be independently associated with delirium onset: restraint use, antipsychotic administration, and the midazolam dose administered.\textsuperscript{23}

**Modifiable Risk Factors**

Although baseline risks for delirium (i.e., those factors present at the time of ICU admission) are usually not modifiable, several environmental and medication-related factors shown to increase the
risk of delirium in critically ill adults are often reversible. The nonpharmacologic delirium risk factors of greatest importance include patient immobilization, application of patient restraints, excessive ambient noise, and admission to an ICU room without windows, clocks, and other features conducive to the maintenance of orientation and circadian normalcy.

**Drug-Associated Delirium**

Several medications used in the ICU may cause or worsen delirium (Table 8.2). Factors that have been shown to predispose patients to drug-induced delirium include (1) the number of agents administered (greater than three); (2) pharmacokinetic derangements, whether associated with aging, organ dysfunction, or drug interactions; (3) medical comorbidities such as dementia or stroke, which are associated with impaired integrity of the blood-brain barrier; and (4) the use of psychoactive medications. Suggested mechanisms for drug-induced delirium include an excess of dopamine, norepinephrine, and glutamate release together with both increased and decreased serotonergic and γ-aminobutyric acid (GABA) activity. The diagnosis of drug-induced delirium is challenging and is generally one of exclusion based on temporal onset and offset relationships. Heightened awareness of the potential for a deliriogenic effect is required for drugs in which a clear temporal relationship is not seen.

Given that medication exposure, the presence of delirium itself vary over each day that a patient spends in the ICU, complex, time-dependent models are needed to evaluate the association between medication exposure and delirium occurrence in critically ill adults. Thus, an increasing number of time-dependent, multivariate analyses focused on evaluating the association between medication exposure (including benzodiazepines, corticosteroids, and anticholinergics) and the daily odds of transitioning from an awake and non-delirious state to delirium the next day have been published. Although a dose-related association between benzodiazepine exposure and a daily transition to delirium has been
reported in several investigations,\textsuperscript{26-28} one recent analysis failed to show an association between anticholinergic drug exposure and a daily transition to delirium.\textsuperscript{30} Although one analysis of patients with acute lung injury (ALI) found that exposure to corticosteroid therapy was associated with a greater odds of transitioning to delirium,\textsuperscript{29} a much larger analysis of critically ill adults both with and without ALI was unable to show such an association.\textsuperscript{31} Although the results of negative association studies like these suggest that the association between a medication class and delirium is likely very low, they cannot rule out that an association does not exist.

Medications remain an important cause of delirium in the critically ill population. If the use of an “at-risk” medication cannot be avoided, the lowest dose of the medication should be prescribed, and the duration of therapy should be as short as possible.\textsuperscript{24} Common strategies that can be used to reduce medication-associated delirium are presented in Box 8.1.

**DELIRIUM PREVENTION**

Given that risk factors for ICU delirium may be modifiable, a careful preemptive evaluation of environmental and medication-related risk factors associated with delirium should be made, and active prevention strategies should also be considered for all patients.\textsuperscript{9,21}

**Nonpharmacologic Strategies**

The evidence to use nonpharmacologic delirium prevention strategies in critically ill adults is far stronger than that available to support the use of a pharmacologic prevention strategy.\textsuperscript{9} With sedative-induced coma being an important risk factor for delirium, strategies focused on maintaining patients in an awake (or lightly sedated) state such as SAT or the use of a sedation protocol are critical to use.\textsuperscript{9} Early patient mobilization (which can only be completed in a patient who is awake) reduces both the incidence and the duration of delirium and significantly increases the likelihood that patients after hospital discharge will return to their pre-ICU functional state.\textsuperscript{32} Frequent reorientation and daytime environmental stimulation reduce delirium incidence.\textsuperscript{33} Sleep deprivation and fragmentation is an important risk factor for delirium; thus, protocols focused on improving sleep quality (e.g., reduced nighttime stimulation/procedures, use of earplugs, prevention of daytime napping, opening of window shades during the day) have been shown to reduce delirium but, of interest, not to improve sleep quality.\textsuperscript{27,34}

**Pharmacologic Strategies**
The 2013 Society of Critical Care Medicine pain, agitation, and delirium guidelines do not advocate that a pharmacologic intervention be used to prevent delirium in critically ill adults.\textsuperscript{9} Currently, no medication has been approved by the U.S. Food and Drug Administration for the prevention of delirium in the ICU. One recent randomized, placebo-controlled pilot study of 68 critically ill, mechanically ventilated adults with subsyndromal delirium in the first 48 hours of ICU admission found that administering haloperidol 1 mg intravenously every 6 hours did not prevent a transition to delirium and was associated with important safety concerns.\textsuperscript{35} A well-designed, but underpowered, multicenter, randomized controlled trial of delirium prophylaxis with either haloperidol or ziprasidone, versus placebo, showed no benefit with either treatment group compared with placebo.\textsuperscript{36}

Other randomized studies have evaluated a medication-based delirium prophylaxis strategy but only in patients undergoing a surgical procedure, primarily elective, who generally have a short duration of postsurgical ICU care.\textsuperscript{37} There is no evidence to suggest that the perioperative use of dexmedetomidine prevents delirium in the ICU. In the largest ICU delirium pharmacologic prophylaxis study published to date, Wang et al. found that a low-dose infusion of haloperidol administered for 12 hours after major abdominal surgery reduced the incidence of delirium from 23\% to 15\% (\textit{p}=0.03).\textsuperscript{38} Of note, however, the severity of illness of these patients was low, and most spent less than 24 hours in the ICU. Further research to better define the safety and efficacy of dexmedetomidine and both typical and atypical antipsychotics is currently under way.

**DELIRIUM TREATMENT**

Removal or reduction of delirium risk factors is the most important strategy when resolving delirium and the symptoms and burden associated with it.\textsuperscript{9,21} Mnemonics such as “I-C-U-D-E-L-I-R-I-U-M-S” can be used by clinicians to help remember the common risk factors and causes for delirium in the ICU when evaluating a patient who has developed delirium in an effort to identify potentially reversible causes
To date, seven prospective, randomized studies have evaluated various drugs to treat delirium in critically ill patients (Table 8.4). The impact of each potential delirium-reducing intervention was reported in one or more of four different ways: presence of delirium at the end of treatment period (n=4), time to delirium resolution (n=2), duration (or time patients had delirium) (n=3), and severity of delirium (n=1).

### Antipsychotics

Of the four studies evaluating the efficacy of an antipsychotic for the treatment of delirium, only one showed a difference in any of these outcomes. In this small pilot study, patients with delirium who were being treated with haloperidol were randomized to additionally receive either quetiapine 50 mg or placebo every 12 hours. The quetiapine dose was increased by 50 mg if more than one dose of haloperidol was given in the previous 24 hours. All patients were allowed to receive haloperidol 1–10 mg every 2 hours as needed. Delirium resolved faster in patients administered quetiapine and resulted in patients spending less time with delirium. This study has many limitations, including its small size and the fact that all patients in the placebo group received one or more intravenous doses of haloperidol. Evidence therefore remains weak to support the routine use of antipsychotic therapy for the treatment of delirium in any ICU patient population, particularly for ICU patients with delirium who are not acutely agitated.

Despite a relative lack of evidence to support the use of an antipsychotic agent to manage delirium and recent ICU practice guidelines that do not recommend their use, antipsychotics are commonly administered in the ICU to patients with either proven or suspected delirium. This persistent high use is likely the result of a belief among clinicians that delirium is predominantly a neurotransmitter-mediated process, a greater familiarity with older delirium guidelines that advocate for antipsychotic use, the challenge of managing agitation in a patient with delirium, and a dramatic under-
appreciation of the risks associated with these agents.

Cholinesterase Inhibitors

One multicenter, randomized, placebo-controlled study that evaluated rivastigmine for the treatment of delirium was terminated early because rivastigmine was associated with greater mortality. In addition, there was a trend for a longer duration of delirium with the use of rivastigmine. Cholinesterase inhibitors should never be used to prevent or treat delirium in any ICU patient population.

Box 8.1. Strategies to Reduce Medication-Related Delirium in the ICU

- Avoid polypharmacy and ensure that medication dosing is appropriate
- Consider medication withdrawal
- Avoid anticholinergic medications when possible
- Avoid benzodiazepines when possible (including sleep aids)
- Use the lowest effective corticosteroid dose
- Use the lowest effective opioid dose to control pain/optimize non-opioid analgesics
- Avoid metoclopramide when possible
- If delirium occurs with levetiracetam (Keppra), consider other anticonvulsant options
- Reassess need for continued antibiotic therapy
- Monitor diuretic therapy for signs of dehydration and/or electrolyte abnormalities

Dexmedetomidine

Among four large, randomized studies comparing dexmedetomidine and benzodiazepine sedation strategies,\textsuperscript{40-42,48} two of the studies that evaluated the presence of delirium each day found that patients receiving dexmedetomidine were less likely to continue to have delirium at the end of therapy.\textsuperscript{41,42} However, these data analyses are inconclusive about whether benzodiazepine use raised the risk of delirium, or dexmedetomidine use reduced the risk, and thus, further investigations are needed to address this question. In one small study of mechanically ventilated patients with agitated delirium, the use of dexmedetomidine, rather than a haloperidol infusion, did not help resolve delirium more rapidly.\textsuperscript{49} Once clinicians address the underlying other potential causes for agitation (e.g., pain, withdrawal) and the modifiable causes for delirium, the proportion of patients with delirium in any ICU who require dexmedetomidine therapy is anticipated to be low.

Future Research

Sufficiently powered, carefully designed, multicenter trials that incorporate a true placebo arm are needed to address the hypothesis that antipsychotics are beneficial in the treatment of delirium in critically ill patients. More recently, it has been suggested that delirium treatment studies should focus on evaluating the effect of antipsychotic therapy on the outcomes that are of greatest importance to patients such as duration of mechanical ventilation, length of hospitalization, or functional status after discharge.\textsuperscript{50}
Practice Recommendations

The 2013 guidelines of the Society of Critical Care Medicine on pain, agitation, and delirium make several important statements and recommendations surrounding delirium in critically ill adults (Box 8.2). In ICU patients who develop delirium, the presence of underlying risk factors for delirium should be removed or reversed whenever possible. Among ICU patients with delirium who are agitated, ensure that the patient is not in pain or experiencing opioid or sedative withdrawal. In a patient with delirium who is agitated enough to require continuous sedative therapy, institute dexmedetomidine, particularly if the patient is currently receiving continuous benzodiazepine therapy. For patients who have milder agitation or who have other symptoms of delirium bothersome to the patient (e.g., fear, delusions), low-dose intravenous haloperidol (8 mg/day or less) should be considered. In a patient who cannot tolerate an oral or enteral medication or who has corrected QT (QTc) interval prolongation that precludes haloperidol administration, quetiapine should be considered. In a patient who cannot tolerate oral or enteral therapy, particularly in one who has QTc interval prolongation, intravenous valproic acid (i.e., 500 mg intravenously × 1; then 50–100 mg intravenously every 6 hours) has been reported in a small case series to reduce delirium-associated agitation.

QUALITY IMPROVEMENT CONSIDERATIONS

Use of a Protocolized ABCDEF Approach

A multidisciplinary, ICU bundled approach (e.g., the ABCDEF bundle) should be used to recognize and reduce delirium in the ICU. This requires that all patients be evaluated for delirium by a member of the ICU team at least once per shift and that the results of these evaluations be documented in the patient record. The ICU team should discuss the results of delirium assessments, strategies to reduce potential modifiable ICU delirium risk factors, and the use of nonpharmacologic strategies to reduce delirium incidence and burden.
at least daily on patient care rounds.

A protocolized, integrated management approach that also includes the assessment of pain (in addition to sedation and delirium), automatic sedation-minimizing strategies (such as daily interruption), and an early mobilization strategy has been shown to significantly improve patient outcomes by reducing the duration of mechanical ventilation and ICU length of stay; avoiding the complications associated with inadequate or inappropriate management of pain, agitation, and delirium; and decreasing health care costs.9,22

Role of Pharmacists

Pharmacists play an important role in helping to boost delirium recognition efforts, recognize risk factors for delirium that may be present (particularly medications), and educate the ICU team on the general lack of evidence supporting pharmacologic interventions to either prevent or treat delirium.9,37,46 For patients who are initiated on antipsychotic therapy, a plan to either decrease or discontinue these agents should be made before the patient leaves the ICU.

### Box 8.2. Recommendations Related to Delirium in the 2013 SCCM Pain, Agitation, and Delirium Guidelines

#### Delirium outcomes

Delirium is associated with increased mortality in adult ICU patients (A).

Delirium is associated with prolonged ICU and hospital lengths of stay in adult ICU patients (A).

Delirium is associated with the development of post-ICU cognitive impairment in adult ICU patients (B).
Detecting and monitoring delirium

We recommend routine monitoring for delirium in adult ICU patients (+1B).

The Confusion Assessment Method for the ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC) are the most valid and reliable delirium monitoring tools in adult ICU patients (A).

Routine monitoring of delirium in adult ICU patients is feasible in clinical practice (B).

Delirium risk factors

Four baseline risk factors are positively and significantly associated with the development of delirium in the ICU: pre-existing dementia, history of hypertension, history of alcoholism, and a high severity of illness on admission (B).

Coma is an independent risk factor for the development of delirium in ICU patients (B).

Conflicting data surround the relationship between opioid use and the development of delirium in adult ICU patients (B).

Benzodiazepines may be a risk factor for the development of delirium in adult ICU patients (B).

There are insufficient data to determine the relationship between propofol use and the development of delirium in adult ICU patients (C).

Delirium prevention

We provide no recommendation for using a pharmacological delirium prevention protocol in adult ICU patients, as no compelling data demonstrate that this reduces the incidence or duration of delirium in these patients (0,C).
We do not suggest that either haloperidol or atypical antipsychotics be administered to prevent delirium in adult ICU patients (-2C).

We provide no recommendation for the use of dexmedetomidine to prevent delirium in adult ICU patients, as there is no compelling evidence regarding its effectiveness in these patients (0,C).

**Delirium treatment**

There is no published evidence that treatment with haloperidol reduces the duration of delirium in adult ICU patients (No Evidence).

Atypical antipsychotics may reduce the duration of delirium in adult ICU patients (C).

We do not recommend administering rivastigmine to reduce the duration of delirium in ICU patients (-1B).

We do not suggest using antipsychotics in patients at significant risk for torsades de pointes (i.e., patients with baseline prolongation of QT interval, patients receiving concomitant medications known to prolong the QT interval, or patients with a history of this arrhythmia) (-2C).

We suggest that in adult ICU patients with delirium unrelated to alcohol or benzodiazepine withdrawal, that continuous IV infusions of dexmedetomidine rather than benzodiazepine infusions be administered for sedation to reduce the duration of delirium in these patients (+2B).

LEARNING OBJECTIVES

1. Understand the pharmacokinetics of neuromuscular blocking agents (NMBAs) and important drug interactions associated with their use, and appreciate their pharmacologic characteristics when used in the critical care and surgical settings.

2. Know the evidence for use of NMBAs for various clinical indications in critical care and surgery.

3. Understand how to monitor these agents in the critical care and surgical settings.

4. Be aware of special populations that require caution in relation to dosage and unpredictable response when administering NMBAs.

5. Appreciate the controversy surrounding the association between NMBAs and intensive care unit–acquired weakness.

6. Know when to reverse NMBAs, know which NMBAs can be reversed, and understand how to choose a reversal agent.

ABBREVIATIONS IN THIS CHAPTER

ARDS Acute respiratory distress syndrome
INTRODUCTION

Curare is a generic term for various poisons applied for centuries by South American Indians to the tips of their arrows when hunting animals. Reports of its use spread to Europe during the Spanish conquest of South America and were relayed in the book De Orbe Novo by Peter Martyr d’Anghiera of the Spanish Court in 1516. New World explorers noted how the Indians ate the meat of the poisoned animals and remained unaffected, because “the poison only kills if it enters the blood,” an oblique reference to the drug’s lack of oral absorption. The modern clinical use of curare apparently dates from 1932 when Ranyard West used highly purified fractions in patients with tetanus and spastic disorders. In the 1930s, Squibb isolated, purified, and marketed curare as Intocostrin, releasing some samples for research purposes early in 1940. Around this time, Lewis H. Wright, an anesthesiologist, suggested its use as a relaxant during surgery, and in 1942, Harold Griffith of Montreal used it successfully, launching the
drug in, and firmly establishing its role as an important adjunct to, anesthesia.\textsuperscript{1-4}

Despite its unfavorable cardiac effects, tubocurarine was popular for years in the practice of anesthesia. In 1952, succinylcholine, the sole depolarizing agent in use today, was introduced, and it is still used because of its desirable pharmacokinetic profile (rapid onset and short duration). However, it can cause severe, although uncommon adverse drug events such as malignant hyperthermia, masseter muscle rigidity, bradycardia and hyperkalemia, and, more commonly, myalgia. The focus of attention has been to find an agent with a pharmacokinetic profile similar to that of succinylcholine without the adverse effects. In that endeavor, pancuronium, an aminosteroid, was synthesized, and it became available in the later 1960s. It has a pharmacokinetic profile similar to that of tubocurarine but with less histamine-releasing and ganglionic-blocking properties and with mild vagolytic properties; the accompanying cardiac stability was appealing. The search for a drug with a profile ideal for surgery continued—short onset and duration, safety in renal and hepatic impairment, minimal cardiac adverse effects—leading to agents such as vecuronium, atracurium, cisatracurium, and rocuronium, all of which are currently in use today.\textsuperscript{1,5}

Apart from a shorter duration of action, the newer agents have greatly diminished the incidence of adverse effects, chief of which are ganglionic blockade, block of vagal responses, and histamine release. Mivacurium, no longer widely used in the United States, is extremely sensitive to catalysis by acetylcholinesterase or other plasma hydrolases, therein accounting for its short duration of action.\textsuperscript{1} Although the adverse effects of these agents are considerably less than those of their predecessors, their pharmacokinetic characteristics still fall well short of “ideal” for use in surgery, and the quest for the ideal agent continues. The clinical use of neuromuscular blocking agents (NMBAs) has expanded beyond the domains of surgery and emergency medicine to the intensive care unit (ICU), where, in addition to management of patient-ventilator dyssynchrony, they may show promise in areas such as acute respiratory distress syndrome (ARDS), increased intracranial and abdominal pressures, and the targeted temperature management
of post-cardiac arrest patients.

BACKGROUND

Anatomy of the Neuromuscular Junction

A somatic lower motor neuron and the skeletal muscle fibers it innervates form a motor unit. A single motor unit may innervate hundreds or, as in the case of large muscles, thousands of muscle fibers. The efferent neuron of the motor unit originates in the ventral horn of the spinal cord and ends at the synaptic bouton, where it loses its myelin sheath and branches out in a terminal arborization in apposition to a specialized area on the muscle cell known as the muscle end-plate. The nerve terminal and muscle endplate constitute the neuromuscular junction (NMJ). The terminal neural bouton contains the neurotransmitter acetylcholine stored internally in vesicles docked at the presynaptic membrane. Each vesicle stores a quantum of acetylcholine, in the range of 1,000–50,000 molecules, and each terminal has 300,000 or more vesicles. Across the synaptic cleft, the nicotinic receptors are largely confined to the endplate on the muscle cell; rarely are they expressed extrajunctionally except in denervation, a condition characterized by increased muscle responses. Acetylcholinesterase is concentrated near the synaptic folds close to the nicotinic receptors, strategically placed so that it can inactivate free acetylcholine immediately, preventing it from recombining with the receptor. Butyrylcholinesterase (pseudocholinesterase or plasma cholinesterase), present in low amounts in glial or satellite cells and responsible for the metabolism of succinylcholine, is virtually absent from the NMJ. In the resting state, there is a continual slow release of isolated quanta of acetylcholine, seen as small depolarizations (i.e., miniature endplate potentials that maintain low-level activity, particularly important because skeletal muscle lacks any inherent tone).\(^6\)-\(^8\)

Physiology
For muscle contraction to occur, the impulse is conducted from the somatic cell body in the ventral horn along the length of the axon in rapid saltatory fashion to the NMJ, where it is transmitted chemically across the synaptic cleft.\textsuperscript{7} Very few pharmacologic agents block axonal conduction in therapeutic doses except for local anesthetics; it is also blocked by puffer fish toxin. When the action potential invades the nerve terminal, it causes local depolarization, increasing calcium permeability through presynaptic voltage-gated calcium channels. Increased intracellular calcium stimulates fusion of vesicles to the membrane and exocytosis of acetylcholine into the synapse. Several hundred quanta are released synchronously, representing several million acetylcholine molecules. Calcium is crucial for release; it forms a complex with a protein, synaptotagmin, which in turn promotes exocytosis of the docked vesicles and formation of a pore through which the acetylcholine can egress. A lack of calcium and an increased magnesium will inhibit this process, magnesium presumably by competing with calcium at the presynaptic site. In addition, magnesium decreases the sensitivity of the postsynaptic nicotinic receptor to acetylcholine.\textsuperscript{6-10} It appears that a small proportion of vesicles are immediately releasable, whereas a much larger reserve pool can be mobilized more slowly. With repetitive stimulation, the amount of acetylcholine released decreases rapidly because immediate stores are exhausted quickly; to sustain release during high-frequency stimulation, vesicles must be mobilized from the reserve pool. Although not in the release process directly, secretion of acetylcholine is enhanced by positive feedback stimulation of homologous presynaptic nicotinic receptors at the NMJ. This serves to maintain the availability of acetylcholine when demand for it is high (e.g., during tetany). Botulinum toxin and some Clostridium toxins block this release process. From 1 to 4 million acetylcholine molecules are released at a time, but only a small fraction of the nicotinic receptors, between 1 and 10 million, require activation for muscular contraction, showing the large margin of safety for successful neurotransmission.\textsuperscript{1,7,8,11-13} Certain medications interfere with transmission at the NMJ (see Figure 9.1; Table 9.1).
The Nicotinic Receptor

The nicotinic receptor belongs to a superfamily of ionotropic receptors that conduct primarily sodium, cause depolarization, and are excitatory. They are found in specific regions of the brain, autonomic ganglia, and skeletal muscle fibers. The nicotinic receptor is the prototype for pentameric ligand-gated ion channels and is composed of four distinct transmembrane spanning subunits (2α:1β:1γ:1δ) that surround an ion channel. Acetylcholine binds to only two of the five subunit interfaces, αγ and αδ. The acetylcholine binding site on the receptor is intimately coupled with an ion channel; simultaneous binding of two agonist molecules is necessary for activation and results in a rapid conformational change that opens the channel. At the motor endplate in skeletal muscle, the receptor is present at high densities in a regular packing order and is virtually absent from the adjacent extrajunctional sites.1,6,7,9

On receptor activation by acetylcholine, the intrinsic channel opens for about 1 millisecond, permitting around 50,000 sodium ions to traverse inward and a smaller amount of potassium ions outward. A localized depolarization or miniature endplate potential ensues; each miniature endplate potential reflects stimulation of a defined number of nicotinic receptors activated by one quantum of acetylcholine. After nerve stimulation, several miniature endplate potentials result and can summate to produce an endplate potential, which, when it reaches threshold, will trigger the muscle action potential by stimulating voltage-gated sodium channels located perijunctionally. The action potential is generated by a rapid influx of sodium ions, but the channels are inactivated quickly, resulting in termination and repolarization. Because of their all-or-none nature and refractory periods, action potentials, unlike end-plate potentials, cannot summate, and a stronger stimulus cannot produce an action potential of greater amplitude. The muscle action potential propagates along the membrane and, in turn, stimulates voltage-gated, calcium dihydropyridine channels, which are coupled to ryanodine receptors on the apposing sarcoplasmic reticulum. This increases intracellular calcium, culminating in contraction of the muscle.6,7
Figure 9.1 Sites of action of pharmacologic agents at the neuromuscular junction and adjacent structures.

The sequence of events leading to voluntary muscle contraction are depicted, and the agents that modify the process are shown on the right. An arrow marked with an X indicates inhibition or block; an unmarked arrow indicates enhancement or activation. The insets are enlargements of the indicated structures, where B depicts the nicotinic receptor.

MECHANISM OF ACTION AND PHARMACOLOGIC EFFECTS
Neuromuscular blocking agents are divided into depolarizing and nondepolarizing (ND) or competitive agents. The competitive or ND NMBAs include pancuronium, vecuronium, rocuronium, mivacurium, atracurium, and cisatracurium; succinylcholine is the only depolarizing agent in use. The development of NMBAs has been driven by their use in surgery, and in this case, the ideal agent should have minimal cardiac and other adverse effects, a rapid onset, a duration of action sufficiently long to last the procedure, and a predictable and quick offset. Select pharmacologic characteristics of currently available NMBAs are summarized in Table 9.2.

Mechanism of Action

ND NMBAs

At the NMJ, the nicotinic receptor is functionally closed in the resting state and opens when two acetylcholine molecules bind to the α sites to elicit an excitatory miniature endplate potential. Competitive antagonists bind to the receptor and block acetylcholine, and this will progressively diminish the amplitude of the endplate potential, which may fall to 70% or less before it is insufficient to initiate a muscle action potential and subsequent contraction. This, together with the fact that only a few receptors are required for activation despite the large amount of acetylcholine released, demonstrates the aforementioned safety factor in neurotransmission. The redundancy is reflected further in animal studies, which have shown that the threshold is around 75% and 95% receptor occupancy for onset of clinically evident and complete block, respectively. Binding is mutually exclusive, and unlike agonists, only one antagonist molecule is required for effect. Acetylcholine is metabolized quickly by acetylcholinesterase in the synapse and does not have the opportunity to rebind with the receptor and compete with the ND NMBA. Nondepolarizing NMBAs also act at presynaptic nicotinic receptors to decrease further release of neuronal
acetylcholine, and this is thought to contribute to the phenomenon of fade seen with the competitive agents during repetitive and tetanic stimulation. The mechanism of fade, a gradual and diminished response with repetitive stimulation, has not been fully elucidated, but ND NMBAs are thought to prevent mobilization of vesicles to the presynaptic membrane for docking and thus acetylcholine from being made available fast enough to support tetanic or train-of-four (TOF) stimulation. At higher concentrations, competitive antagonists block the channel directly in a fashion that is noncompetitive with agonists and dependent on membrane potential.\textsuperscript{1,11,14} Fade and post-tetanic stimulation are notable characteristics of competitive block. The mechanism underlying the latter, where a TOF applied after titanic stimulation results in an augmented response, is presumably because after the tetanic stimulation, more of the stored acetylcholine is mobilized to the docking area and is available for release with subsequent stimulation—in this case, TOF—so that the competitive block can be overcome. Moreover, in contrast to depolarized block, competitive block can be reversed using acetylcholinesterase inhibitors.\textsuperscript{8,9}

**Depolarizing NMBAs**

Succinylcholine, the only depolarizing agent currently in use, operates in a different fashion that is less well understood. Like acetylcholine, it depolarizes the membrane and activates sodium channels in the muscle, which is manifested as a brief initial period of fasciculation. Unlike acetylcholine, succinylcholine persists at the NMJ for a longer period because it is metabolized by butyrylcholinesterase, which is virtually absent at the NMJ, leading to a longer-lasting depolarization. Block ensues because the desensitized state of the nicotinic receptor is promoted as a self-regulatory mechanism after prolonged exposure to the agonist, which in turn and for similar reasons, inactivates the perijunctional voltage-gated sodium channels. After succinylcholine administration, a sequence of repetitive stimulations (fasciculations), followed by block of transmission and neuromuscular paralysis, is elicited and has been called phase 1 block. Any agonist, including
acetylcholine, if permitted to activate the membrane for an extended period, can initiate this series of events culminating in block. Acetylcholine is metabolized so rapidly by acetylcholinesterase, however, that it is not normally relevant. Competitive and depolarizing blocks are distinguishable. In contrast to competitive agents, there is no additive blocking effect for depolarizing agents with ND NMBAs; acetylcholinesterase inhibitors do not reverse it, initial fasciculations are seen, and there is a well-sustained contraction after tetanic stimulation during partial block. In some animals and occasionally in humans, depolarizing agents produce a blockade with unique features, some of which combine characteristics of competitive and depolarizing agents, which is thus termed dual mechanism block. Under clinical circumstances in humans, with increasing concentrations of succinylcholine and over time, the block may slowly convert from a depolarizing to an ND type, termed phase 1 and phase 2 blocks, respectively. Characteristics of ND block described earlier emerge in phase 2, such as the phenomenon of fade and antagonism by acetylcholinesterase inhibitors.1,6,9,11,15

**Pharmacologic Effects**

**Extra-NMJ Actions**

Most extra-NMJ actions associated with the NMBAs occur because of cross-reactivity and histamine release resulting in adverse effects, most notably those of a cardiac nature.9

**Cross-reactivity**

All of the NMBAs can potentially cross-react with extrajunctional nicotinic and muscarinic receptors in the body. Apart from pre- and postjunctional sites, nicotinic receptors are also present in autonomic ganglia and prejunctional effector sites of the sympathetic nervous system, in which they increase norepinephrine release. Muscarinic receptors are found in postjunctional para-sympathetic nervous system effector sites, autonomic ganglia, presynaptic sympathetic effector
sites in which they decrease norepinephrine release, and blood vessels. Muscarinic type 2 (M\textsubscript{2})-receptors promote bronchodilation and bradycardia, whereas muscarinic type 3 (M\textsubscript{3})-receptors produce bronchospasm.

N/A = not applicable.

The older agent, tubocurarine, has the greatest affinity for ganglionic nicotinic receptors. Pancuronium has significant blockade at muscarinic M\textsubscript{2}-receptors in the parasympathetic nervous system and at presynaptic muscarinic receptors in the peripheral sympathetic nervous system, with the former resulting in vagolytic action and the latter increasing norepinephrine release, both of which cause tachycardia. Rocuronium has affinity for the vagus and other peripheral muscarinic receptors in the parasympathetic nervous system, more so than vecuronium. The remaining ND agents have even weaker affinities for the muscarinic receptor. The most significant manifestation of these extrajunctional actions is tachycardia; bronchoconstriction is not reported with any frequency, probably because of the equal antagonism of pulmonary M\textsubscript{2}- and M\textsubscript{3}-receptors. The depolarizing
agent, succinylcholine, has affinity for nicotinic and muscarinic receptors at ganglionic and vagal sites, respectively; see Cardiac Effects below. 16-21

Cardiac Effects

Cardiac effects are the major adverse events associated with the older agents curare and succinylcholine and are related to histamine release and cross-reactivity at extrajunctional cholinergic receptors, causing peripheral autonomic and ganglionic effects. 16, 22 The capacity to cause these effects is found with all available agents, although it varies considerably among them and may not be seen at clinical doses. Among ND NMBAs, pancuronium and atracurium have the greatest potential to cause adverse cardiac effects. The following mechanisms may apply:

1. Histamine release. Originally seen with curare, histamine release is predominantly found with the use of atracurium, mivacurium, and succinylcholine. Pancuronium use releases minimal amounts of histamine and cisatracurium, virtually none. Histamine release has not been seen with rocuronium. Isolated reports of vecuronium-induced histamine release have not been confirmed, even with high doses, although hypotension and flushing have been reported after vecuronium administration and may be related to decreased histamine catabolism through inhibition of histamine N-methyltransferase. The phenomenon is associated with large doses and rapid administration of NMBAs; therefore, it is less likely to occur with the doses administered in ICU regimens. It can be prevented by slowly injecting the agent over 1–3 minutes or by pretreating with histamine-1 (H1) and histamine-2 (H2)-receptor antagonists. Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than immunoglobulin E (IgE)-mediated anaphylaxis. 8, 16, 23-33

2. Vagolytic actions. Vagolytic actions are most prominent with pancuronium use and result in mild and dose-dependent
tachycardia. However, this is a significant enough adverse effect to recommend avoiding its use in patients with coronary artery disease because of the risk of increased myocardial ischemia, ventricular extrasystoles, and, as reported in one case, cardiovascular collapse. Rocuronium also has affinity for vagal receptors, which manifests as tachycardia. Theoretically, this is also true of vecuronium, but to a much lesser degree, and there is little reference to it in the literature. Clinically, vecuronium has relatively little effect on the heart. Curiously, bradycardia has been reported with its use, although a causal relationship is not always evident. The mechanism for this is unclear but may be related to vagal stimulation (see mechanism 5 in this section). Cisatracurium may also block M₂ vagal receptors, but clinical tachycardia does not appear to be important. Atracurium and mivacurium lack any appreciable vagolytic effects.¹⁶-¹⁸,3⁴-⁴⁸

3. Ganglionic blockade. Ganglionic blockade is seen with curare, and all agents will demonstrate it if given in large enough doses; pancuronium has weak ganglionic activity at recommended doses. Atracurium, vecuronium, rocuronium, mivacurium, and cisatracurium are even more selective and, in recommended doses, cause minimal, if any, ganglionic blockade. The effect on heart rate depends on the patient’s dominant tone, which at rest is generally vagal (M₂ muscarinic), thus resulting in tachycardia.¹,¹⁶,⁴⁷,⁴⁹-⁵¹

4. Sympathetic stimulation. Sympathetic stimulation is seen with pancuronium. The mechanism is not entirely clear but is probably related to the blockade of various presynaptic muscarinic and nicotinic receptors, which have opposing activities. The net effect is the increased release of norepinephrine causing tachycardia.⁸,⁵²

5. Ganglionic or muscarinic stimulation. Succinylcholine may cause bradycardia through ganglionic or muscarinic stimulation at the vagus,⁸,²² and it has been suggested that vecuronium is also vagotonic when administered concurrently with potent opioids.⁵³-
Malignant Hyperthermia

Malignant hyperthermia, a channelopathy, is a rare genetic disorder triggered by exposure to depolarizing NMBAs (succinylcholine) and inhalation anesthetics containing halogenated hydrocarbons, and it has a mortality rate of 80% if left untreated. The offending agent superimposes a change in the host’s genetically altered ryanodine receptor, resulting in an uncontrolled efflux of calcium from the sarcoplasmic reticulum with subsequent tetany, increased skeletal metabolism, and heat production. Onset usually occurs within 1 hour of, and rarely up to 11 hours after, administration. Early features of malignant hyperthermia are tachycardia, cyanosis, and muscle rigidity, which is most prominent in the masseter muscle. Marked hyper-thermia occurs hours later, commonly accompanied by hypotension, dysrhythmias, rhabdomyolysis, electrolyte abnormalities, disseminated intravascular coagulation, and mixed acidosis. Rarely, patients have rhabdomyolysis without hyperthermia.\textsuperscript{1,57-69} Conventionally, it is diagnosed using the classical caffeine halothane contracture test (in North America) and in vitro contracture test (in Europe), but these are expensive and invasive. Curiously, a recent pilot study (n=24) suggested that lymphocyte adenosine levels present a diagnostic alternative. Evidently, lymphocytes contain the same ryanodine receptor as muscle cells and, in the presence of high amounts of intracellular calcium, lead to activation of ATP-dependent calcium pumps, producing free adenosine as a by-product. Compared with controls, there was marked accumulation of adenosine in lymphocytes from susceptible individuals, providing a potential diagnostic marker for malignant hyperthermia in affected individuals.\textsuperscript{70}

Treatment, which should dissipate heat quickly to prevent death, involves rapid cooling, giving 100% oxygen, controlling acidosis, and administering intravenous dantrolene, which blocks calcium release from the sarcoplasmic reticulum and decreases myoplasmic free calcium concentration, culminating in decreased muscle tone and heat production. With early diagnosis and treatment, recovery occurs in
virtually 100% of patients.\textsuperscript{65,71-73}

**Histamine Release and Immediate Hypersensitivity Reactions**

Immediate hypersensitivity reactions are classified as immune- or nonimmune-mediated, the most severe appearing as anaphylaxis. Allergic anaphylaxis is commonly mediated by IgE binding to the FCeRI receptor on mast and other immune cells, culminating in the release of inflammatory mediators such as histamine, tryptase, prostaglandins, leukotrienes, and several chemokines and cytokines. Non-immune anaphylaxis is thought to be caused by direct stimulation of mast cells and basophils releasing inflammatory mediators as a result; it does not entail the immune system, and thus, previous exposure is not required. Although previous sensitization is a prerequisite for allergic anaphylaxis to occur, it is not obligatory, and sensitization may occur through cross-reactivity. Specific IgE assays and skin testing are available to test for NMBA sensitivity. Intraoperative anaphylaxis is a rare but significant event, and NMBA are the drugs most commonly implicated. It is usually IgE mediated, and quaternary and tertiary ammonium ions are considered the epitopes. However, other chemical characteristics such as hydrophobicity as well as flexibility of the molecule may be involved. More-flexible molecules like succinylcholine are considered more antigenic than the aminosteroids, which are quite rigid and bulky. Cross-reactivity occurs between the NMBA themselves and with unrelated drugs and foods that possess the common ammonium ion structure. There are reports that pholcodine, a cough suppressant with a structure similar to the quaternary ammonium ion in NMBA, and used in Europe but not in the United States, may be incriminated in the sensitization process. This offers one explanation for the differing prevalence of rocuronium-induced reactions according to geographic location: some European countries where pholcodine use is high have higher rates of sensitivity; in contrast, the reported rates are extremely low in the United States, where the drug is not available.\textsuperscript{74,75}

Histamine release per se, most evident with succinylcholine, atracurium, and mivacurium, can be reduced by slowing the rate of NMBA administration and giving smaller doses. Histamine-induced
Cutaneous reactions occur in 5%–10% of patients receiving atracurium and do not necessarily indicate that more-serious effects will follow. Pretreating with H$_1$- and H$_2$-antagonists may also reduce histamine release. Rapid injection of 0.6 mg/kg or greater of atracurium besylate causes clinically significant hypotension, tachycardia, bronchospasm, and flushing. Cisatracurium causes less histamine release than atracurium, and the effect is insignificant in recommended doses.

The pertinent questions for the clinician are (1) which NMBA is least likely to cause anaphylaxis in routine practice and (2) what is the likelihood of cross-reactivity to other NMBAs. These questions were addressed in a recent study from Australia, in which the investigators confirmed similar reports from France that anaphylaxis to rocuronium is emerging and relatively prevalent. In this retrospective study (n=80), investigators analyzed patients who had a documented immediate-type sensitivity reaction during surgery and who underwent subsequent skin testing to the NMBA used and other possible triggering agents. Strict criteria needed to be fulfilled before applying the diagnosis of NMBA anaphylaxis. Cross-reactivity testing to other agents was also done. Investigators reviewed patients over a 10-year period from 2002 to 2011 and calculated exposure rates from purchasing data, which were available for the second 5-year period of the study and extrapolated to the full 10-year span. Their results showed that NMBAs are common triggers of anaphylaxis in anesthesia in Western Australia; rocuronium may be associated with a higher incidence compared with other NMBAs and had a 3-fold increased risk of IgE-mediated anaphylaxis compared with vecuronium. Although a rate could not be computed for succinylcholine—purchasing data were not reliable in determining exposure rates because of the common practice of wasting half-used vials—cross-reactivity results suggested that it also has a high incidence of triggering anaphylaxis. As regards cross-reactivity, cisatracurium had the lowest incidence in patients with previous anaphylaxis to rocuronium or vecuronium, and the authors suggested its consideration in such cases. Although the study was well designed, there were some limitations, including retrospective nature, small
numbers, extrapolation of exposure rates from purchasing data and from a 5-year period, and possible referral bias.

**ICU-Acquired Muscle Weakness**

A group of neuromuscular disorders that is now recognized in critically ill patients with multiple organ dysfunction syndrome commonly occurs and is characterized by generalized muscle weakness and failure to wean from mechanical ventilation (MV). The muscular weakness previously attributed to starvation-induced or disuse atrophy is now ascribed to the adversely affected functions of peripheral nerves, NMJs, and skeletal muscles in the critically ill and has been collectively called critical illness polyneuropathy and myopathy (CIP/M). Neuromuscular blocking agents, especially if used in combination with corticosteroids (CS), may contribute to the development of CIP/M, though the evidence is conflicting. Neuro-muscular blocking agents may alternatively cause intensive care unit–acquired weakness (ICUAW) because of prolonged neuromuscular blockade as a result of reduced drug clearance. The latter, a protracted therapeutic effect secondary to impaired elimination of the NMBA as a result of either organ dysfunction or drug interactions, can manifest as weakness but is without overt pathology.

**Critical Illness Polyneuropathy and Myopathy**

Critical illness polyneuropathy (CIP) and critical illness myopathy are major complications of severe critical illness and its management and may significantly prolong weaning from MV and patient rehabilitation. The patho-physiology is complex and unclear. It has been hypothesized that a disturbance in the microcirculation caused by sepsis, cytokines, and/or hyperglycemia, or a combination of these, is central to its etiology (see Figure 9.2). As mentioned, CIP/M encompasses weakness caused by polyneuropathy, a motor and sensory axonal neuropathy, and a common complication of severe sepsis, by myopathy, which has been reported with the use of CS and NMBA and by NMJ dysfunction. Histologically, CIP is primarily distal axonal
degeneration with no evidence of demyelination or inflammation and typically presents as sensorimotor polyneuropathy. Critical illness myopathy, in contrast, encompasses a spectrum of pathologies including acute necrosis, regeneration, type 2 fiber atrophy, and selective but patchy loss of thick filament/myosin.\textsuperscript{82-85} Thick-filament myopathy and myonecrosis with sensory function remaining intact has been described in patients receiving NMBAs in combination with CS. Although it is unclear whether NMBAs are associated with weakness when not coadministered with steroids, Bolton and others\textsuperscript{83} suggested that such an entity, manifesting as polyneuropathy, exists when NMBAs are given in the presence of sepsis. In general, the aminosteroids, pancuronium and vecuronium, were implicated; whether this reflects a prevalence in their use at the time or is related to their similarity in structure to steroids is unclear. This notwithstanding, sepsis was thought by the authors to be the main etiologic event, with the role of NMBAs being merely contributory. Other reports identifying NMBA-associated weakness do not always clarify whether CS were coadministered.\textsuperscript{84,86-100}
Several studies have investigated the relationship between NMBAs and myopathy, each with some limitation. All of these are either case reports or small observational studies, retrospective or prospective, with heterogeneous populations and drug regimens. Techniques for diagnosing myopathy varied; in addition, baseline characteristics were not always compared, and in some, the use of NMBAs was very low or for a very short duration.\textsuperscript{97,101} Furthermore, the details on CS and
sedative use are not always clear, potentially introducing confusion. Overall, the results are conflicting. Four studies documented the emergence of myopathy in patients with severe asthma who were ventilated and receiving high-dose steroids. These were all of retrospective cohort design; three did not compare severity of illness comprehensively between groups at baseline. Three of the studies found an association between NMBA duration of use and the incidence of ICUAW. Atracurium was implicated equally as often as the aminosteroids, pancuronium and vecuronium. Patients were sicker at baseline in the NMBA group in one study (n=101), and in another, the respiratory illness severity between groups was not illuminated at all (n=86), making interpretation difficult. The fourth study (n=96) did not find an association, but there was a trend toward less weakness with restriction of paralysis, which, according to the authors, could have reached statistical significance if the numbers had been larger; as it was, the study was underpowered to detect it. They concluded, however, that the use of NMBAs is not considered a prerequisite for weakness in patients with asthma on MV; rather it is immobilization that, whatever the cause, most likely constitutes the final common pathway. Two case reports of near-fatal patients with asthma on MV and high-dose CS merit mention. One of these treated three such patients, all of whom received NMBAs for at least 7 days. Biopsy revealed necrosis. All three had previous admissions where they received MV and CS in the absence of NMBAs and had no sign of weakness, implicating NMBAs in the index visit. The details of sedative administration were lacking, however, for previous admissions, thus limiting the comparison. In a prospective case series of 44 critically ill patients, Coakley et al. found that weakness occurred in patients regardless of NMBA administration. Some patients received both CS and NMBAs (11 of 44). Numbers were too small to draw a definite conclusion, but the authors believed that if used judiciously, NMBAs could be used safely. Much of the published literature accounting for NMBA-associated myopathy involves patients with asthma, but there are also, albeit limited, data in patients with sepsis receiving NMBAs alone. Witt et al. (n=43) evaluated the risk
factors associated with CIP/M in patients with sepsis and found no association with NMBAs, but these agents were only rarely used in this study, rendering any inference invalid. Instead, the authors found a clear correlation between CIP/M and ICU length of stay, serum albumin, and blood glucose in patients with sepsis having multiple organ dysfunction. Garnacho-Montero et al. (n=73) found an association between NMBAs and ICUAW in an earlier observation study of patients with sepsis but failed to confirm this in a later study (n=64). Again, there were several confounders in these two studies, including sepsis and coadministration of sedatives; also, NMBA usage was low in the earlier trial, and details on dosage regimens were not elaborated on in either study. Segredo et al., in a prospective observational cohort design, studied 16 critically ill ventilated patients with pulmonary infection and/or sepsis who had received at least 2 consecutive days of vecuronium. They identified weakness clinically and by peripheral nerve stimulation/train-of-four (PNS/TOF) monitoring; electrophysiologic studies were not done. Seven of the 16 study patients had “prolonged block,” and the incidence of renal failure was higher in that group of patients. However, bicarbonate and pH were significantly lower, magnesium was reduced, and renal failure was more common in the weak group, confounding the picture and rendering interpretation difficult. Furthermore, sedative doses were not revealed, which could be influential. The authors suggested that it was prolonged blockade, but they could not rule out CIP/M as a cause because they did not test for it.

Finally, in three relatively recent, well-conducted, large, randomized controlled trials (RCTs), a short course of cisatracurium, less than 48 hours, in patients with ARDS was not associated with ICUAW. In summary, in small observational studies, NMBAs in conjunction with CS have commonly been implicated in the development of ICUAW, manifesting as a quadriplegia, the underlying pathology generally being a myopathy with sensory function intact. Intensive care unit–acquired weakness is purportedly related to the dose and duration of NMBAs. However, study results on this issue of association with ICUAW are not unanimous in their affirmation. Thus, although a
common perception, the evidence that NMBAs cause ICUAW is not conclusive, and more standardized large prospective trials are needed to identify the risk factors.\textsuperscript{106,110,111} In the interim, it is prudent to use these agents for a short duration in critically ill patients in the ICU and to monitor them closely.

Other Pharmacologic Effects

Succinylcholine increases intragastric pressure; however, it increases lower esophageal sphincter pressure even more, such that aspiration is unlikely unless the esophageal sphincter is incompetent. Succinylcholine can also increase intraocular and intracranial pressures. Fasciculations and hyperkalemia may develop after succinylcholine, especially in sensitive patients with up-regulation of NMJ receptors. The risk is increased during prolonged depolarization with succinylcholine, where muscle cells may lose significant quantities of potassium and gain sodium, chloride, and calcium. The loss of potassium can be critical in patients receiving continued administration of succinylcholine who have had extensive soft tissue injuries. Succinylcholine-induced hyperkalemia can be life threatening in patients with congestive heart failure receiving digoxin or diuretics, and its use is contraindicated or should be done with great caution in patients with nontraumatic rhabdomyolysis, ocular lacerations, spinal cord injuries with paraplegia or quadriplegia, or muscular dystrophies.\textsuperscript{1,8,9,112}

PHARMACOKINETICS

Relative efficacy of these agents is measured quantitatively as the ED95. The ED95 is the average dose needed to produce 95% suppression of the adductor pollicis twitch response to ulnar stimulation; the intubation dose ranges from 1 to 3 times the ED95, depending on the NMBA. The dose range reflects a difference in sensitivities between muscle groups. However, the dose, as well as other pharmacokinetic parameters such as onset and duration, also depends on cardiac output and muscle blood flow, indicating that a muscle’s response is not always a reflection of its sensitivity alone.
Various pharmacokinetic values are shown in Table 9.2; onset and duration are dose-dependent. Duration of effect is organ-dependent for pancuronium; for vecuronium and rocuronium, it is also related to redistribution; and for atracurium, cisatracurium, succinylcholine, and mivacurium, it is governed by metabolism in the plasma.\textsuperscript{8,9,11,113,114}

A critical number of receptors must be occupied before a drug can elicit an initial response. Thus, less-potent agents tend to have a faster onset than more-potent ones because a greater concentration is available to block spare receptors—the comparison between rocuronium and cisatracurium can be made. The duration of action is defined as the time from drug administration to the time when the evoked neuromuscular function of the thumb returns to 25% baseline, and the recovery time index is the time from 25%–75% twitch recovery of the adductor pollicis muscles.\textsuperscript{8,9,114} Pharmacokinetic activity for NMBAs may vary in older adults, which may be related to age-related differences in cardiac output resulting in decreased clearance. Succinylcholine, which is metabolized by liver and plasma butyrylcholinesterase, may have modest prolongation of action in hepatic failure, in patients who have an atypical plasma cholinesterase or a deficiency of the enzyme owing to allelic variations or pregnancy, and with high doses (e.g., greater than 2 mg/kg of succinylcholine) because of slow diffusion from the NMJ.\textsuperscript{1,8,11,115,116} Cisatracurium and atracurium are metabolized by ester and Hofmann elimination to laudanosine and to a mono-quaternary acrylate, both of which may be toxic, although the levels associated with cisatracurium may be 1/10th those with atracurium.\textsuperscript{8,11,117} There have been rare reports of seizures after prolonged infusions of atracurium,\textsuperscript{8,11,117-121} presumably because of laudanosine's activity at the \(\gamma\)-aminobutyric acid receptors, although evidence is scant. Clinically, laudanosine concentrations may not reach adequate levels to produce this effect. In general, atracurium and cisatracurium are better suited for patients with organ dysfunction. Hypothermia and acidosis decrease the clearance of atracurium and cisatracurium because Hofmann elimination is pH- and temperature-dependent. Accumulation in renal failure is seen with pancuronium, vecuronium, and possibly, albeit to a lesser degree, rocuronium after
several doses. Vecuronium and rocuronium may accumulate in patients with hepatic failure and severe disease, respectively, because of decreased biliary uptake. Moreover, rocuronium’s volume of distribution may be increased in hepatic disease, further prolonging its duration and onset of action.8,9,11,122,123

INDICATIONS FOR THE ICU

Whereas the ideal NMBA in surgery should have a rapid onset and duration of action as well as minimal cardiac adverse effects, such characteristics are not as critical for use in the ICU. In fact, a longer duration may be preferred if a prolonged effect is desired, and in such cases, the aminosteroids may be administered (i.e., pancuronium or vecuronium). The benzylisoquinoline agents, atracurium and cisatracurium, offer the unique advantage of being independent of kidney and liver function for clearance, an important consideration and thus a popular choice in critically ill patients. Proposed adjunctive applications for NMBAs in the ICU include the following: improving chest wall compliance, eliminating ventilator dyssynchrony, reducing intra-abdominal pressures,124,125 preventing and treating shivering during therapeutic hypothermia, and preventing elevations in intracranial pressure from airway stimulation. Select indications are discussed in the sections that follow (see Table 9.3 for summary of studies discussed).

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome is characterized by intense lung inflammation, consolidation, and progressive microatelectasis and is associated with severe hypoxemia, ventilator dyssynchrony, barotrauma, and ventilator-induced lung injury. Low tidal volume ventilation has been shown to improve survival in ARDS, and other strategies such as high positive end-expiratory pressure, prone ventilation, and the use of NMBAs may have merits.126-129 There is interest in elucidating the role NMBAs may play, if at all, in the
management of ARDS. In this capacity, several trials, varying in quality of design, have evaluated the use of NMBAs.\textsuperscript{107-109,130-132} Three noteworthy RCTs, all from the same authors (n=431), addressed the use of cisatracurium in mechanically ventilated patients with early ARDS for a 48-hour duration in several ICUs in France.\textsuperscript{107-109} Cisatracurium administration was weight based and guided by TOF in two studies,\textsuperscript{108,109} and in the third,\textsuperscript{107} it was given as a fixed, high dose of 37.5 mg per hour without adaptation to PNS. A subsequent meta-analysis of these studies was done by a separate group, but they collaborated with the original authors to gain further clarification and access to unpublished data.\textsuperscript{133} Combining the three trials, they deemed the quality of evidence related to mortality as moderate and limited because of nonblinded caregivers, and the evidence related to ICUAW weak because it relied solely on clinical diagnosis.\textsuperscript{133} Otherwise, the results were large, precise and consistent across studies. In this meta-analysis, a 48-hour infusion of cisatracurium consistently reduced mortality at 28 days, in addition to mortality at ICU discharge and at hospital discharge. The incidence of barotrauma was similarly reduced, with the duration of MV and the risk of ICUAW not being affected. The mortality reduction findings associated with NMBA therapy were large and robust; the authors determined that for every nine adults with ARDS treated with cisatracurium, one life was saved in the first 90 days of hospital admission. Duration of MV was not significantly different between groups; however, in those receiving NMBAs, ventilator-free days were increased, the latter of which was thought to be because of competing risks of death and duration of MV. Mechanisms responsible for this improvement may be related to improved oxygenation; reduced inflammation (whether indirect or direct remains to be elucidated); and improved synchrony.\textsuperscript{108,109,126,133} These results are somewhat echoed in a study\textsuperscript{134} published in the Chinese literature comparing vecuronium for 24–48 hours in patients with ARDS and severe sepsis with controls (n=48), where the authors found decreased mortality and improvement in morbidity with the treatment group. For this chapter, the source for these results was confined to the abstract because it was the only section translated into English,
thus restricting the interpretation. In summary, early short-term use of cisatracurium for the treatment of ARDS shows promise; more RCTs are needed to substantiate existing findings.

**Status Asthmaticus**

Many small studies and case reports have been published evaluating various aspects of treating patients with asthma when an NMBA is included in the regimen. The mortality rate may be too low in patients with severe asthma receiving MV for it to serve as an end point, however, because a very large sample size would be required to assess an effect on survival. Therefore, other outcomes or composite outcomes were sought to assess efficacy or risk-benefit relationships in this population. Four studies, including the aforementioned three, evaluated NMBA therapy in patients with severe asthma on MV; however, only one was designed to address mortality as part of a composite outcome, and the remaining three examined the association of NMBA with ICUAW. In addition, these patients were all deeply sedated and receiving CS, which could have misguided data interpretation. In the study by Adnet et al. (n=101), NMBA use was the strongest independent factor for the composite outcome of ICU death, multiple organ failure, pneumonia, and paresis. Three studies showed increased ICUAW with prolonged duration of administration. Atracurium held no advantage over the aminosteroids. Kessler et al. (n=96) compared patients receiving NMBA regimens of much shorter duration with those on long-duration therapy and did not find a significant decrease in weakness with therapy of short duration, although an association with NMBA therapy of longer duration was the trend, and the authors believed it would have reached significance had the study population been sufficiently large. Nevertheless, they opined that in patients who are deeply sedated and mechanically ventilated, immobilization is inevitable and is itself an important contributor to the etiology. Overall, because of the paucity of information in this population, it is recommended that NMBAs be reserved for those with severe gas-trapping and lung hyperinflation
that is life threatening and refractory to other therapies.\textsuperscript{122}

**Increased Intracranial Pressure**

Control of increased intracranial pressure is fundamental to the treatment of patients with head injury, and sedatives and analgesics play an important pharmacologic role. In a retrospective review of data from the National Traumatic Coma Data Bank (n=514), early, routine, long-term use of NMBAs in patients with severe head injuries to manage increased intracranial pressure did not improve overall outcome and may actually have prolonged ICU stay and increased extracranial complications.\textsuperscript{135} Although NMA use was associated with fewer deaths (p<0.001), the group receiving them had a higher incidence of sepsis, pneumonia, and more vegetative or severely disabled survivors. A second large retrospective study (n=326)\textsuperscript{136} found no difference in mortality or length of stay between patients with traumatic brain injury, whether they received NMBAs or not. Other smaller studies focusing on physiologic changes have shown that, in general, NMBAs do not affect hemodynamic parameters such as intracranial, mean arterial, and cerebral perfusion pressures but may attenuate acute changes in these variables during suctioning.\textsuperscript{137-140} Because of design limitations, the current body of evidence does not provide a conclusive answer, and a recommendation for their use in increased intracranial pressure cannot be made. In general, NMBAs in this population should be selective and considered only when deep sedation is insufficient to prevent dangerous elevations in intracranial pressure (e.g., during suctioning or with sudden cough or shivering).\textsuperscript{122,141,142}

</table>
### Targeted Temperature Management After Cardiac Arrest

In the early 2000s, two clinical trials evaluated mild hypothermia for 12–24 hours in which body temperature was reduced to 32°C–34°C in comatose survivors of cardiac arrest, and pancuronium or vecuronium was part of the protocol to reduce shivering. Neurological outcomes and mortality were improved.\(^{143,144}\) Several years later when Chamorro
et al.\textsuperscript{145} investigated ICU protocols for targeted temperature management of post-cardiac arrest patients worldwide, the authors found that NMBAs were commonly used for preventing and/or treating shivering. There was considerable variation with respect to the type of NMBA used, regimens, and monitoring habits. Pancuronium was the most commonly used, with usage in 24 of 68 participating ICUs. Cisatracurium was second, being included in 14 of the 68 ICU protocols. Train-of-four monitoring was used in three of the ICUs and continuous monitoring of cerebral activity in only three. Status epilepticus is a recognized risk in postanoxic injury, and diagnoses may be difficult when the patient is paralysed; indeed, status epilepticus occurred in 25 of 68 ICUs with an incidence of 0\%–44\%. Still, the value of continuous electroencephalogram monitoring in predicting prognosis and guiding management has yet to be confirmed in this population.\textsuperscript{146}

However, there are no prospective controlled studies comparing the efficacy of NMBAs in this population (i.e., a direct comparison between an NMBA group and a non-NMBA group or between various NMBAs). Salciccioli et al.\textsuperscript{147} (n=111) did a post hoc analysis of a prospective observational trial of comatose patients after cardiac arrest where the primary exposure of interest was neuromuscular blockade for 24 hours, and primary outcomes were in-hospital survival and functional status at discharge. They showed an increased probability of survival and improvement in lactate clearance, a secondary outcome. There was a trend toward improved functional outcome. Limitations included small size, observational design, post hoc analysis, and potential for bias. In a retrospective study comparing vecuronium with cisatracurium use in cardiac arrest patients, Baker et al.\textsuperscript{148} (n=201) examined the association between NMBA use and neurological outcome. After multivariable regression analysis, computation of the adjusted odds ratio for good neurological outcome showed that cisatracurium was the only independent variable with positive association (p=0.014). Similarly, limitations applied to this study because it was retrospective in nature, and the groups were not prespecified so that baseline characteristics could have differed between them. Multivariable regression analysis was done to minimize such inherent bias. Moreover, the numbers were
small and unequal between groups (60 received cisatracurium, and 36 received vecuronium), and details of regimens, including total dose administered, were not explicit. The authors suggested that pharmacokinetic differences accounted for these variances because vecuronium relies on organ function for clearance, which may be impaired in these patients, whereas cisatracurium does not. It could be argued, however, that the clearance of cisatracurium, which is achieved by Hofmann elimination and in itself is temperature-dependent, would be expected to be impaired in the hypothermic condition, thus challenging this notion. In general, it is acknowledged that hypothermia to this degree per se may reduce the clearance of all NMBAs; however, the comparative order of magnitude is unknown in this population because most of the data are derived from cardiopulmonary bypass patients. Further studies are required to evaluate the role and choice of NMBAs in targeted temperature management before a definite recommendation can be given.

Otherwise, if using NMBAs for this indication, the impact of hypothermia on pharmacodynamics and pharmacokinetics must be considered. As mentioned earlier, the effects of NMBAs may be amplified during hypothermia, and doses may typically be 20%–25% less, although other authors have described resistance to NMBAs as well as differing pharmacologic results. For example, Heier et al. found no difference in the pharmacodynamic effects of vecuronium in hypothermic versus normothermic intraoperative patients. It must be stated, however, that first, the temperature difference was relatively small between groups in this study (34.4°C vs. 36.8°C), and second, the degree of hypothermia attained was not as low as the convention (i.e., to 32°C–33°C, a common range). The authors did not investigate pharmacokinetic changes in this study, so we cannot comment. However, Cammu et al. found a reduction in cisatracurium, but not rocuronium, infusion rates in mildly hypothermic intraoperative patients (33°C). Because the elimination of cisatracurium is known to be temperature-dependent, this may account for the difference. Because of the different underlying populations in these studies, however, it is probably imprecise to extrapolate these
intraoperative findings to the hypothermic post-cardiac arrest patient. Further concerns arise when monitoring the hypothermic patient on NMBAs. For example, PNS may be less accurate because the twitch tension may be dampened and may correlate poorly with degree of blockade. It is important to be aware of this blunting of response in cooled patients when using PNS and to supplement its use with clinical assessment such as elimination of shivering. As alluded to, the other consideration is that NMBAs may mask seizure activity. Although the emergence of seizure activity is a sign of worse outcomes in these patients, controlling them has not yet been shown to improve neurologic prognosis.

**Increased Intra-Abdominal Pressure**

Intra-abdominal hypertension is defined as a repeated elevation in intra-abdominal pressure of at least 12 mm Hg. Acute compartmental syndrome is defined as continued intra-abdominal pressure of greater than 20 mm Hg with end-organ dysfunction or failure. Reduced abdominal wall compliance caused by third-spaced fluids, tense abdominal closures, and pain or inadequate sedation can lead to further increases in intra-abdominal pressures and subsequent organ failure. Neuromuscular blocking agents have been reported to improve elevated intra-abdominal pressures by reducing abdominal muscle tone. Neuromuscular blockade may provide clinicians with more time to remove fluid or treat the underlying cause of intra-abdominal hypertension and avoid surgical decompression. A small prospective trial (n=10) suggested that a bolus dose of cisatracurium was effective in significantly decreasing mild elevations in intra-abdominal pressure. A recent case report describing a patient undergoing adrenalectomy who had acute compartmental syndrome reported that a prolonged NMBA infusion of 48 hours was effective in reducing intra-abdominal pressure and providing a good recovery. It has been recommended (grade 2C) by the International Acute Compartment Syndrome Consensus Definitions Conference Committee that NMBAs be used in selected patients to reduce mild to moderate
elevations in intra-abdominal pressure.\textsuperscript{153,154}

**Sepsis**

Several studies evaluating the use of NMBAs in patients with sepsis examine adverse outcomes such as ICUAW as end points rather than clinical efficacy and mortality (see ICU-Acquired Muscle Weakness section).\textsuperscript{96,99,101} In contrast, Steingrub et al.\textsuperscript{100} reviewed the impact of NMBA administration in ICU patients with pulmonary sepsis on MV where the primary outcome was in-hospital mortality. This was observational in nature involving 339 centers (n=7,864), and the authors used robust methods to adjust for known and suspected confounders by sensitivity analysis, using regression and instrumental variable analyses and propensity matching. Secondary outcomes included the number of days on MV and hospital and ICU lengths of stay. Intensive care unit–acquired weakness was also assessed and was based on ICD-9-CM codes, which is a list of codes adapted by the U.S. healthcare system to describe diagnoses. Results showed a significant reduction in hospital mortality with NMBA use (risk ratio [RR] 0.88; 95\% confidence interval [CI], 0.80–0.96). There was a low incidence of ICUAW. By nature of its design, the investigation suffers from bias and other limitations. First, because of confounding, the demonstrated improvement in mortality may have been related more to an overall center effect because of differing degrees of success in implementing evidence-based practices between hospitals (e.g., lung-protective ventilation and early goal-directed therapy) rather than NMBA use itself. Second, the study used detailed billing data and ICD-9-CM codes instead of chart review, a fact likely to influence the incidence of ICUAW as a result of undercoding. Third, it was difficult to separate NMBA administration used for procedures and NMBAs used for long-term treatment, prompting a sensitivity analysis restricted to those on NMBA treatment for at least 2 days or on a total daily dose suggestive of an infusion. In this case, the investigators found no difference; indeed, they even found a trend (nonsignificant) toward higher mortality associated with NMBA use (RR 1.10; 95\% CI, 0.91–
1.33), further highlighting the need for caution in interpreting and extrapolating the results in “causal” terms.\textsuperscript{157} It must be declared, however, that the unanimity of results computed using several different analytic techniques lends greater credence to the mortality findings in the primary outcome of this study. Clearly, more prospective studies are needed to confirm these claims.

**INDICATIONS FOR USE IN SURGERY**

Neuromuscular blocking agents, which have rapid onset and offset and minimal cardiac effects, are ideal for surgical procedures. Apart from their use in the operating theater, NMBAs have other applications in the anesthesia/surgical setting such as rapid sequence intubation, priming doses, and defasciculation.

**Rapid Sequence Intubation**

Rapid sequence intubation is used to secure a definitive airway in uncooperative, unfasting, unstable, and/or critically ill patients who may be at risk of aspiration. The anesthetist needs to intubate quickly before the anesthetic takes effect and the gag reflex is lost.\textsuperscript{158-160} It is important to have an NMBA with a fast onset, and succinylcholine is commonly used to accomplish this. However, some patients are excluded from receiving it because of undesirable adverse effects (see Introduction and Pharmacologic Effects), so it is important to have an alternative. In this endeavor, rocuronium has been compared with succinylcholine in several trials and in a subsequent meta-analysis of these trials. In one prospective RCT (n=401), no difference was noted in oxygen desaturations between succinylcholine and rocuronium in critically ill patients undergoing emergency rapid sequence intubation.\textsuperscript{161} In the meta-analysis,\textsuperscript{160} data from 37 controlled trials (n=2,690) were reviewed, comparing the quality of intubating conditions provided by rocuronium and succinylcholine. There was a dose effect: in the subgroup of patients receiving rocuronium 0.6–0.7 mg/kg, there was a relative risk favoring succinylcholine for excellent intubating
conditions (RR 0.81; 95% CI, 0.73–0.90), and the number needed to harm was 6. There was significant heterogeneity between the studies in this subgroup. In the groups that received 0.9–1.0 mg/kg of rocuronium and 1.2 mg/kg of rocuronium, there were no statistical differences for excellent or acceptable intubation conditions; however, succinylcholine, which had the advantage of a shorter duration of action, was thus ultimately deemed superior. There was no significant heterogeneity between the studies in the 0.9- to 1.0-mg/kg or 1.2-mg/kg rocuronium subgroups. Overall, the results showed that succinylcholine was superior to rocuronium (RR 0.86; 95% CI, 0.8–0.97), and the authors concluded that rocuronium’s role should be relegated to that of an alternative agent. Typical doses for succinylcholine in this capacity are 1 mg/kg but may be as high as 2 mg/kg, especially in children. The usual range for rocuronium is 0.6–1.2 mg/kg.⁸

An acetylcholinesterase inhibitor should be available if intubation is unsuccessful; this does not apply when succinylcholine is being used. With succinylcholine, a patient’s history should be known so that the risks of hyperkalemia and malignant hyperthermia may be minimized. Dantrolene should also be available during short procedures if succinylcholine is the chosen agent.¹⁵⁹

**Priming Strategy**

Nondepolarizing NMBAs can also be administered in “priming” doses in an effort to overcome their slow onset. Theoretically, by giving small priming doses, the spare receptors are blocked without the patient having clinical weakness. The priming dose is generally considered to be 10% of the ED95, although there is no exact consensus on this detail.¹⁶²-¹⁶⁴ Ideally, the patient should be able to breathe spontaneously and maintain an open airway in order to avoid aspiration after a priming dose. After about 4 minutes, a large bolus is given, decreasing the time to paralysis from 3–5 minutes to 70–100 seconds, comparable to succinylcholine. The clinician needs to closely monitor the patient and be ready to intubate in an emergency when using
priming doses. In a small randomized trial of female patients undergoing anesthesia induction (n=30), Schmidt et al.\textsuperscript{164} compared the effect of a priming technique with a bolus application of rocuronium on the onset of NMBA at the laryngeal adductor and the adductor pollicis muscles. After transcutaneous stimulation of the recurrent laryngeal nerve and ulnar nerve, a bolus of rocuronium 0.6 mg/kg (bolus group) or a priming dose of rocuronium 0.06 mg/kg, followed by rocuronium 0.54 mg/kg 3 minutes later (priming group), were injected. Lag time, onset 90%, onset time, and peak effect of NMBA were recorded and compared. The onset 90% and onset time measured at the laryngeal adductor muscles (onset was 44.7 ± 7.4 vs. 74.0 ± 23.8 seconds) and at the adductor pollicis (onset was 105.4 ± 29.9 vs. 139.2 ± 51.5 seconds) were significantly shorter in the priming group than in the bolus group, indicating that a priming technique with rocuronium significantly accelerated the onset of NMBA at the laryngeal adductor muscles. Under clinical circumstances, however, the technique is limited because some patients become profoundly weak after the priming dose, necessitating prompt control of ventilation and giving concern for aspiration.\textsuperscript{159,165} Just as some individuals will be quite sensitive to priming doses of ND NMBA, others will show resistance. Enthusiasm for the priming technique has been tempered with time, mainly because response is unpredictable.\textsuperscript{162}

**Defasciculation Strategy**

Using ND NMBA as agents to prevent fasciculations is another strategy in surgery. After administration of the depolarizing agent succinylcholine, muscle fasciculations occur briefly, particularly over the chest and abdomen; then, relaxation occurs within 1 minute, becomes maximal within 2 minutes when transient apnea may occur, and disappears, as a rule, within 5 minutes.\textsuperscript{1} Severe muscle soreness may follow succinylcholine administration. Applications of small doses of competitive NMBA before succinylcholine have been used to minimize such fasciculations with attendant muscle pain and possibly hyperkalemia, although the practice is controversial because it may
increase requirements for succinylcholine.

The defasciculating dose is generally 10% of the ED95 and is given 3–5 minutes beforehand. Rocuronium has been administered in this capacity (0.03–0.04 mg/kg or 10% of the ED95) where it decreased the incidence of fasciculations from 90% to 10%. A recent meta-analysis shows that adverse effects of weakness have commonly occurred in studies of defasciculating doses of ND NMBAs, but these adverse effects are probably related to higher doses (e.g., rocuronium 0.06 mg/kg). After the defasciculating dose of ND NMA, the succinylcholine dose must be increased from 1 mg/kg to 1.5 mg/kg, or even 2 mg/kg, because of antagonism between ND and depolarizing drugs. Administering small doses of succinylcholine (e.g., 10 mg 1 minute before the intubating dose) appears ineffective in this respect and has largely been abandoned.

**INTERACTIONS WITH NMBAS**

Several conditions as well as many drugs interact with NMBAs, most importantly inhalation anesthetics, certain antimicrobials, calcium channel blockers, and acetylcholinesterase inhibitors. The mechanisms are broadly outlined in Table 9.1. There may be additive interactions if two NMBAs of similar structure are given together (e.g., atracurium-cisatracurium), or the effect can be potentiated if NMBAs of dissimilar structure are coadministered (e.g., rocuronium/cisatracurium). Administering small doses of NMBAs before succinylcholine can prevent fasciculations caused by succinylcholine, a practice called administration of defasciculating doses (see Defasciculation Strategy section). In contrast, administering succinylcholine before ND NMBAs has given conflicting results, some reporting potentiation of block and others seeing no effect at all.

Aminoglycosides interact by inhibiting acetylcholine release from the presynaptic terminal (through competition with calcium) and, to a lesser extent, by noncompetitively blocking the postsynaptic receptor. The blockade is antagonized by calcium salts but only inconsistently by
acetylcholinesterase inhibitors. The tetracyclines cause blockade, possibly by chelation of calcium and polymyxin B; colistin and clindamycin do so by both pre- and postsynaptic actions. Calcium channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. It is unclear whether this is a result of a diminution of calcium-dependent release of transmitter from the nerve ending or whether it is a postsynaptic action. When co-administering these drugs with NMBAs, dose adjustments should be considered; if recovery of spontaneous respiration is delayed, calcium salts may facilitate. Magnesium interacts significantly probably only at doses used for treating preeclampsia.\textsuperscript{1,11} Miscellaneous drugs that may have significant interactions with either competitive or depolarizing NMBAs include opioid analgesics, procaine, lidocaine, quinidine, phenelzine, phenytoin, propranolol, magnesium salts, CS, digitalis glycosides, chloroquine, catecholamines, and diuretics. Dantrolene blocks release of calcium from the sarcoplasmic reticulum and is used in the treatment of malignant hyperthermia (see Malignant Hyperthermia section). Acidosis and hypothermia may produce unpredictable effects with ND NMBAs. However, hyper-calcemia, demyelinating lesions, peripheral neuropathies, and diabetes have been reported to antagonize ND NMBA because of up-regulation of extrajunctional receptors.\textsuperscript{1,9,123,174-176}

\textbf{MONITORING}

\textbf{Peripheral Nerve Stimulation}

After administering an adequate dose of NMBA, motor weakness progresses to a rapid paralysis. Small rapidly moving muscles (e.g., eyes, jaw, and larynx) relax before those of the limbs and trunk. Eventually, the intercostals and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order so that the diaphragm is ordinarily the first muscle to regain function. However, paralysis is affected not only by the differential sensitivity of muscles to block but also by the regional blood
flow. Thus, even though the diaphragm is more resistant to blockade, it receives greater blood flow and drug delivery, permitting a quicker onset of paralysis than that of the adductor pollicis in the thumb. The orbicularis oculi muscle is less sensitive than the adductor pollicis, and its time to paralysis correlates more closely with that of the diaphragm.\textsuperscript{1,9,11,177,178}

The margin of safety for these agents is small because there is little effect until most receptors (spare receptors) are occupied so that the therapeutic range exists over a very narrow range of receptor occupancy (see Figure 9.3).\textsuperscript{1,8,9,11} Peripheral nerve stimulation is generally used to monitor for the potential toxicity of NMBAs in ICU patients, efficacy being better assessed using clinical parameters, such as respiratory variables, in patients with ventilator dyssynchrony. On the contrary, PNS is used to assess efficacy in the operating theater, the goal being to keep the sedated patient completely immobilized. With PNS, a stimulator is applied to a peripheral nerve, and the response of the muscle it innervates is observed. The response to PNS indicates the level of neurotransmission in the muscle of interest, usually the diaphragm, because it cannot be monitored directly. The nerve response to electrical stimulation depends on the current applied (maximum current 60–80 mA), duration for which the current is applied, and position of the electrodes (in that at least one electrode must be placed over the nerve).\textsuperscript{179} The patterns of stimulation vary and elicit different characteristics of ND neuromuscular blockade. For example, when high-frequency stimulation is used, fade and post-tetanic facilitation occur. The use of these patterns applies mainly to ND NMBAs because such responses are not seen with the depolarizing agents. Fade appears to be caused by a decrease in acetylcholine release at the NMJ because the margin of safety for neurotransmission is compromised in the presence of blockade. Although acetylcholine release decreases when high-frequency stimulation is used, even in the absence of blockade, fade is not detected because of the sufficiently wide margin of safety for neurotransmission. The TOF pattern is the most commonly used mode of stimulation in the ICU and surgical settings, where it is interpreted by visual or tactile perception and thus
is prone to error. With TOF stimulation, a supramaximal stimulus is delivered by PNS at a frequency of 2 Hz for 0.2 millisecond; the stimuli are applied in trains of 2 seconds (500 milliseconds apart) at an interval of 10 seconds or greater. This low frequency permits tactile and visual measurement. In theory, the supramaximal stimulus is determined by increasing the current until there is no further increase in response. However, health care providers often obviate this in practice using a maximal current from the beginning. At least 10–15 seconds should pass between stimulations to allow for full repolarization of the nerve.\textsuperscript{8,180-184} Conceptually, we think of muscular response to PNS stimulation in terms of receptor occupancy at the NMJ. Although this conceptualization describes the dose-response relationship as a whole, each muscle fiber in the group has an all-or-none response once a critical number of its receptors are blocked.\textsuperscript{6} In other words, there is no gradual decline in individual fiber responses with increasing doses; rather, there is an all-or-none response, and depending on fiber sensitivity, some will succumb sooner than others to escalating doses. Therefore, although not an accurate representation, receptor occupancy serves a useful purpose in understanding the dose-response relationship. It is envisioned that 75\% of receptors must be occupied before any clinical blockade is seen. Continuing from 75\% to 95\% receptor occupancy, a gradual blockade of transmission is manifested by a decrease in twitch height from 100\% to 0\%, resulting in total blockade of the muscle group.\textsuperscript{185} Train-of-four can be interpreted as a count in which the absolute number of contractions is evaluated visually, manually, or by calculating the TOF ratio (T4 divided by T1), comparing the fourth twitch with the first for intensity and height. The TOF ratio must be quantified by tactile methods, which is difficult, and may require using a transducer for accuracy. Thus, it is not recommended in the ICU.
Figure 9.3  Receptor occupancy and clinical responses.

Receptor occupancy is at least 75% (top panel) before a reduction in response to peripheral nerve stimulation (lower panels) or a change in clinical examination (uppermost text) is evident.

A TOF count of 1/4–2/4 indicates adequate block without undue risk of toxicity. Similarly, a TOF ratio of 0.25 indicates onset of block, and a ratio of 0.75 implies clinical recovery. The TOF ratio is traditionally used postoperatively to assess recovery, but some patients have
weakness at 0.8, whereas others do not recover until a TOF ratio of 0.9 is achieved, which has become the reference for recovery of ventilatory function. Many clinicians fail to detect fade at a TOF ratio of 0.6 during the recovery phase, implying that significant weakness can go undetected. On the contrary, it may be missed by the PNS when a response is seen or felt clinically.\textsuperscript{186,187} Therefore, it is important to do both clinical tests and TOF to assess recovery when patients leave the operating room. Both methods have shortcomings, but if used in combination, they form a more powerful monitoring tool.\textsuperscript{8} Finally, there are several sources of error in interpreting the TOF, including variation between operators, incorrect positioning of the electrode pads, improper attachment of wires to pads, insufficient time for nerve repolarization, inconsistent pressure, and visual versus tactile assessment. All can invalidate the results. Problems arise if the patient is hypothermic, has oily or hairy skin, or has edema on the area where the pads are applied or if the batteries are low and the current is inadequate.\textsuperscript{9,123,184}

In the ICU, TOF monitoring was associated with decreased costs when used to monitor vecuronium, but this did not extrapolate to atracurium and cisatracurium, perhaps because the pharmacology of the latter agents is less affected by organ impairment in critical illness.\textsuperscript{188-190} Because evidence is sparse, it is recommended that PNS monitoring not be relied on exclusively, rather, that clinical parameters be identified (ventilator synchrony, increased chest wall compliance, decreased O\textsubscript{2} consumption) to assess patients on NMBAs and to further guide therapy. Caution in interpreting the TOF is advised when used in hypothermic patients.\textsuperscript{123,149}

**REVERSAL**

In contradistinction to ICU patients in whom reversal agents are rarely used, rapid recovery from neuromuscular blockade is important postoperatively where the rate of recovery is dictated by both the NMBA used (the spontaneous rate) and the reversal agent (the accelerated reversal rate). Residual blockade with a TOF ratio less
than 0.9 may occur in up to 33% of patients arriving in the post-anesthesia care unit. A study by Murphy et al. (n=7,459) suggests that a large proportion of cases of postoperative upper airway obstruction and/or hypoxemia can be attributed to residual neuromuscular blockade. Prevention of residual paralysis depends on judicious neuromuscular blocker management, monitoring, and use of reversal agents. Replacing long-acting drugs with more protracted spontaneous rates of recovery by intermediate agents has been largely accomplished, and monitoring has been improved. Moreover, acetylcholinesterase inhibitors are used to reverse competitive blockade in postoperative patients, further accelerating recovery.

The mechanism of action of acetylcholinesterase inhibitors involves acetylcholinesterase inhibition. Neostigmine and pyridostigmine attach at the esteratic and anionic sites of the acetylcholinesterase molecule and produce longer-lasting inhibition than edrophonium. Neostigmine and pyridostigmine are inactivated by acetylcholinesterase, whereas edrophonium is unaffected. The inhibition of acetylcholinesterase increases the amount of time that acetylcholine spends in the synaptic cleft, leading to the increased size and duration of the excitatory postsynaptic endplate potential. Neostigmine is the most commonly used agent because of the long onset of pyridostigmine and the limited availability of edrophonium. Neostigmine is the most potent of the acetylcholinesterase inhibitors. The dose-response curve reaches a ceiling effect for these drugs at a dose of 0.07 mg/kg of neostigmine or its equivalent for other agents. However, it may even be as low as 0.03–0.05 mg/kg so that neostigmine offers only partial recovery. Neostigmine is more efficacious during intense blockade than the other two agents, and it is effective against all ND NMBAs. It is generally recommended to wait for four twitches on the TOF to appear before administering neostigmine because there is no advantage in the time it takes to gain full recovery by administering it early. In clinical doses, it may unexpectedly produce a degree of blockade, particularly if a second dose is given. This is unlikely with a single modest dose, and any effects are probably short-lived. The mechanism for this effect is unknown, but a possible explanation may be that the muscle
has fully recovered after the first dose and the second dose is acting on normal unblocked muscle, producing an acetylcholine-induced blockade. Mivacurium poses a challenge for reversal. Like succinylcholine, its metabolism may be inhibited by neostigmine, introducing a risk of prolonging blockade. Edrophonium does not inhibit plasma cholinesterase, perhaps making it better suited for the reversal of mivacurium. Muscarinic effects such as bradycardia, increased salivation, and gastrointestinal motility as well bronchoconstriction are common with acetylcholinesterase inhibitors and can be prevented by coadministering anticholinergics. Confusion is also associated with acetylcholinesterase inhibitors. Less than 1% of patients have other central nervous system effects, including dysphoria, restlessness, agitation, seizures, headache, and drowsiness.

Sugammadex, currently unavailable in the United States, is a modified A-cyclodextrin that binds tightly to steroid-based NMBAs such as vecuronium and rocuronium, permitting accelerated removal of the drugs from the plasma and subsequently from the NMJ through an increased concentration gradient. It is ineffective against atracurium and cisatracurium. Sugammadex has no muscarinic effects because it lacks affinity for the acetylcholine receptor. The dose required depends on the amount of NMBA present and thus the degree of block and when adequate doses are given, recovery to a TOF ratio greater than 0.9 is attained in 2–3 minutes. It has few adverse effects and is expensive. Sugammadex has been studied postoperatively and in rapid sequence intubation, but it has not been evaluated in critical care patients.

CONCOMITANT CARE

Awareness during surgery and in the ICU has been described in paralyzed patients. Although there are no controlled studies evaluating the use of sedatives in critically ill patients receiving NMBAs, it is recommended to administer these drugs before commencing and throughout any paralytic regimen. The bispectral index monitor (BIS monitor-Aspect Medical Systems, Covidien, Mansfield, MA) is used to
assess sedation, but it is unclear whether awareness can totally be avoided by its use because large doses of NMBAs can depress the bispectral index in certain circumstances.\textsuperscript{11,153,205,206}

For completion, the following aspects of care should be attended to in the patient receiving NMBAs: frequent suctioning because the cough reflex is inhibited; light taping and lubrication of the eyes to prevent corneal drying and ulceration; regular turning to prevent decubitus ulcers; elevating the head of the bed to reduce the risk of aspiration, particularly during enteral feeding; and monitoring the pupillary reflexes to assess neurologic status (pancuronium is unreliable in this respect because of its relatively strong muscarinic effects); hyperglycemia should be managed with a target blood glucose of less than 180–200 mg/dL, and venous thrombus and stress ulcer prophylaxis should be instituted.\textsuperscript{122} As alluded to previously, it is crucial to provide adequate sedation and pain relief with sedatives and analgesics because such properties are not within the pharmacologic spectrum of the NMBAs.

\section*{SPECIAL POPULATIONS}

There is some controversy regarding the corresponding effects on recovery when NMBAs are dosed according to actual body weight versus ideal body weight. For atracurium, ideal body weight was considered more predictable with less variability by some authors but not by others.\textsuperscript{207-209} Similarly, Meyhoff et al. and Leykin et al. showed more optimal recovery times when dosing atracurium according to ideal weight, but Puhringer found no statistical difference.\textsuperscript{210-213} The patient population in Leykin’s study was severely obese, however, whereas Puhringer’s patient population was moderately so, which may have accounted for the difference.\textsuperscript{211,214} For both vecuronium and cisatracurium, ideal body weight was more predictable than actual weight.\textsuperscript{209,214} Thus, ideal body weight or some adjusted body weight that accounts for changes in body mass is recommended when dosing patients with obesity.\textsuperscript{8,11}

Sensitivity, particularly to the hyperkalemic effects of succinylcholine, can occur in those with up-regulation and extrajunctional proliferation of
nicotinic receptors beyond the endplate to the sarcolemma. Such up-regulation is seen in denervated muscle caused by acute upper and lower motor neuron disease (spinal cord injury, stroke, demyelinating disease, encephalitis, prolonged immobility with disease, chronic progressive neurologic disease, muscular dystrophies, amyotrophic lateral sclerosis paraplegia, and crush injuries) and in postburn and posttrauma patients.

LEARNING OBJECTIVES

1. Distinguish between the various shock syndromes given a patient’s clinical and hemodynamic parameters.

2. Identify critical determinants affecting oxygen delivery.

3. Construct a hemodynamic monitoring plan that incorporates data from monitoring devices and markers of perfusion.

4. Devise a treatment strategy for the treatment of a patient with hypovolemic or obstructive shock.

ABBREVIATIONS IN THIS CHAPTER

CO Cardiac output
CVC Central venous catheter
CVP Central venous pressure
DO$_2$ Oxygen delivery
LV Left ventricle/ventricular
MAP Mean arterial pressure
PAC Pulmonary arterial catheter
PCC Prothrombin complex concentrate
INTRODUCTION

Shock is a heterogeneous syndrome affecting about one-third of all patients requiring intensive care.\(^1\) Best defined as circulatory failure, shock originates from a mismatch in oxygen delivery (DO\(_2\)) and oxygen consumption (VO\(_2\)). Shock is a heterogeneous syndrome spanning a wide spectrum, beginning with oxygen mismatch. Continued shock ultimately results in end-organ failure and death. The clinical presentation of shock can be subtle in many patients, and the diagnosis of shock is typically based on the interpretation of clinical, hemodynamic, and laboratory findings.\(^2\) In many cases, shock becomes evident in the setting of arterial hypotension, with a systolic blood pressure (SBP) less than 90 mm Hg or a mean arterial pressure (MAP) less than 70 mm Hg. However, these values are arbitrary and population based, possibly leading to under-recognition of the syndrome in select patients. For example, a patient with persistent hypertension and a baseline SBP of 170 mm Hg may have a suboptimal DO\(_2\) with an SBP of 110 mm Hg.

Clinical manifestation of shock can present in a variety of forms. Typically, shock can be identified in gross examination of three distinct end-organ systems: central nervous system (mentation, orientation), renal (urine output less than 0.5 mL/kg/hour), and skin (cold and clammy, reduced capillary refill, decreased skin turgor).\(^2\)
Dysoxia is typified by the development of hyperlactatemia. The exact threshold by which to define hyperlactatemia is variable but is commonly described as greater than 1.5 or 2 mmol/L.\textsuperscript{3,4} When insufficient oxygen is present at tissue beds, lactate and adenosine triphosphate production is promoted through the lactate dehydrogenase pathway.\textsuperscript{5}

The circulatory system serves the vital need of delivering oxygen to promote homeostasis and end-organ function. End-organ function is dependent on a critical supply of DO\textsubscript{2}. In healthy adults, oxygen is inspired and delivered by passive diffusion into the alveoli, where it reversibly binds to hemoglobin, and is taken to the myocardium. Oxygen transportation to the end organs is dependent on stable cardiac output (CO). On reaching the tissue beds, oxygen is taken up by the mitochondria for aerobic metabolism. In advanced shock syndromes, blood flow is redirected from extravital end organs (e.g., skin, gut, kidneys) to prioritize consistent DO\textsubscript{2} to vital organs (e.g., heart and brain). Oxygen delivery is dependent on several tightly regulated variables (Table 10.1).

**HEMODYNAMIC MARKERS AND PERFUSION**

Hemodynamic parameters can directly be measured from noninvasive monitoring devices or invasive monitoring devices, or they can be calculated using direct measurements (Table 10.2).

Mean arterial blood pressure is the driving pressure for peripheral blood flow and is used as a surrogate marker to estimate end-organ perfusion. Mean arterial pressure can be calculated by noninvasive measures using the following equation: \( \text{MAP} = \frac{\text{SBP} + (2 \times \text{DBP})}{3} \). Blood pressure can be measured by auscultation using a sphygmomanometer or oscillometry, or it can be directly measured using an intra-arterial catheter. Noninvasive blood pressure is obtained by inflating the cuff above the patient’s SBP, resulting in occlusion of blood flow and no audible sound on auscultation.\textsuperscript{6,7} The first Korotkoff sound will be heard once the cuff pressure is incrementally reduced to the level of the patient’s SBP. This sound is the result of vibration
caused by the return of intermittent blood flow against the arterial wall. In conditions with high vascular resistance (e.g., cardiogenic shock), there is low venous compliance, resulting in diminished sound formation. Likewise, in conditions with low vascular resistance (e.g., septic shock), low flow results in diminished sound formation. In the setting of shock, blood pressures obtained from auscultation may underestimate the systolic and diastolic blood pressures and are often unreliable. Oscillometry measures the pulsation of the artery wall as a pressure vibration against an inflated cuff. It can be set to automatically cycle, allowing for dynamic monitoring of critically ill patients with shock. The accuracy of this modality largely depends on the appropriate size and fit of the cuff.

---

**Intra-arterial Catheter**

Arterial catheters provide a means for continuous blood pressure monitoring, and they are considered the gold standard monitoring modality for patients who are being treated for shock requiring the administration of vasoactive medications. Arterial catheters are also used for obtaining arterial blood samples to assess pulmonary gas exchange. They are placed under sterile conditions, usually in the radial artery, but they can be placed in the axillary, brachial, femoral, and dorsalis pedis arteries. Complications from arterial access include hemorrhage, access-site hematoma, arterial thrombosis, pseudoaneurysm, and infection.

**Central Venous Catheter**

The central venous catheter (CVC) can be used to measure the central venous pressure (CVP), administer medications and fluids, procure venous blood gases, and perform other laboratory assays. Central venous catheters are placed under sterile conditions into the internal jugular vein, subclavian vein, axillary vein, or femoral vein. Complications from CVC access include pneumothorax, catheter-associated bloodstream infection, hemorrhage, and thrombosis.\(^9\)

Central venous pressure is used interchangeably with right atrial pressure. The utility of CVP as a marker of fluid resuscitation and fluid responsiveness is limited by several variables. It is falsely elevated in patients with tricuspid regurgitation, isolated right ventricular (RV) dysfunction, high pulmonary arterial pressures, and mechanical ventilation because of increased intrathoracic pressure.\(^9\)-\(^{11}\) Central venous pressure is a poor quantitative measure of volume status because its utility in determining fluid responsiveness is lacking.\(^{12}\)-\(^{14}\) Central venous pressure should be used with caution to estimate left ventricular (LV) end-diastolic volume.\(^9\) In one single-center study of 96 patients with severe sepsis or septic shock that looked at the relationship between pre-resuscitation CVP and fluid responsiveness, fluid responsiveness was defined as a rise in cardiac index greater than 15%.\(^{14}\) The authors concluded that a preresuscitation CVP less than 8 mm Hg predicted fluid responsiveness with a sensitivity of 62%, specificity of 54%, and positive predictive value of only 51%. Given the data analyses suggesting mortality improvement in targeting a CVP

\end{align*}
\]

Cao\(^2\) = arterial oxygen content; Cvo\(^2\) = venous oxygen content; DO\(^2\) = oxygen delivery; Hgb = hemoglobin; Pvo\(^2\) = mixed venous oxygen tension; Sao\(^2\) = arterial oxygen saturation; Svo\(^2\) = venous saturation; VO\(^2\) = oxygen consumption.
greater than 8 mm Hg in the early management of sepsis, recent guidelines recommend that the use of CVP as a resuscitation parameter be limited to the brief initial resuscitation period in early sepsis management.\textsuperscript{15,16} However, this recommendation may be reevaluated in light of recent findings inconclusive of previous findings.\textsuperscript{17,18}

**Pulmonary Arterial Catheter**

The pulmonary arterial catheter (PAC; Swan-Ganz catheter) provides several useful hemodynamic parameters, including pulmonary artery systolic pressure; pulmonary artery diastolic pressure; pulmonary capillary wedge pressure (PCWP), also known as pulmonary artery occlusion pressure; and mixed venous oxygen saturation. In addition, CO and systemic vascular resistance (SVR) can be calculated using parameters measured from the PAC. The routine use of PACs to guide therapies has largely fallen out of favor in critically ill patients.\textsuperscript{16} In clinical practice, most PAC use is reserved for patients with advanced heart failure requiring inotropic support, patients with mixed-picture shock to optimize hemodynamics, and patients undergoing cardiothoracic surgery.\textsuperscript{19,20} Complications of PAC include arrhythmia, right bundle branch block, complete heart block in patients with left bundle branch block, pulmonary infarction, infection, thrombus, air embolus, and pulmonary artery rupture.\textsuperscript{21}

Cardiac output is the product of heart rate and stroke volume (SV).\textsuperscript{22} In the presence of normal electrical conduction, heart rate is largely mediated by the autonomic nervous system. In healthy patients, tachycardia does not result in hemodynamic compromise. Conversely, in the setting of shock or myocardial dysfunction, tachycardia results in increased myocardial oxygen demand, decreased diastolic filling time, reduced SV, decreased CO, and decreased coronary artery perfusion. Severe bradycardia can also precipitate a shock syndrome in patients with myocardial dysfunction. Slow heart rate can result in increased ventricular filling and derangement of the Frank-Starling curve in patients with myocardial dysfunction.\textsuperscript{23}

Stroke volume is the volume of blood ejected during systole,
calculated by subtracting the end-systolic volume from the end-diastolic volume. Stroke volume is primarily determined by preload, afterload, and contractility. Preload is the ventricular end-diastolic volume and is directly proportional to SV through the Frank-Starling mechanism. Increased venous return results in a stretch of the myocardial sarcomeres and increased force of contraction. Of note, the Frank-Starling mechanism can have significant derangements in the presence of heart failure with a reduced ejection fraction. Preload is estimated in patients with a PAC using the PCWP. The PCWP requires inflation of a balloon at the distal tip of the PAC that wedges in the pulmonary artery capillary bed during diastole. This results in a static column of blood that connects the tip of the PAC to the left atrium while completely occluding the right heart and pulmonary artery diastolic pressures. Thus, PCWP estimates left atrial pressure and LV end-diastolic pressure (because the mitral valve is open during diastole). Afterload is the arterial resistance to systole. In a heart with normal systolic function, an increase in afterload has little impact on SV. Conversely, in heart failure with a reduced ejection fraction, increased afterload results in decreased SV and increased ventricular end-systolic pressure. The heart has two distinctly different afterloads to overcome. Pulmonary artery systolic pressure and pulmonary vascular resistance mediate RV afterload. Left ventricular afterload is mediated by SVR (also known as total peripheral resistance). Systemic vasoconstriction increases SVR, whereas vasodilation decreases SVR. Contractility is the intrinsic ability of the myocardium to contract. Activation of the sympathetic nervous system or the use of medications with inotropic properties can increase contractility. Heart failure with a reduced ejection, acute myocardial infarction, acidosis, and medications with negative inotropic properties can result in decreased contractility.

</table>
Cardiac output is the volume of blood ejected from the LV per minute.\textsuperscript{22} Because CO is heart rate × SV, CO can be manipulated by altering either variable. Cardiac output can be determined by two means: through thermodilution or using the Fick equation. Thermodilution involves an injection of chilled intravenous fluid with a known temperature into the right atrial port of the PAC and the subsequent measurement of temperature change of the blood in the pulmonary artery.\textsuperscript{27-29} In patients with a reduced CO, more time is required for the temperature to return to baseline, whereas in patients with normal or high CO, blood flow is carried quickly through the heart, and temperature rapidly returns to normal. Thermodilution is not accurate in patients with tricuspid regurgitation, patients with intracardiac shunting, mechanically ventilated patients with high positive end-expiratory pressure, and patients with severely reduced ventricular function. In these patients, the Fick CO is calculated using the equation \[
CO = \frac{[(135 \text{ mL/minute } \text{O}_2/\text{m}^2) \times \text{BSA}]/[13.4 \times \text{hemoglobin} \times (\text{Sao}_2 - \text{Svo}_2)]}{}}\] Fick is considered the gold standard in determining CO; however, it is sometimes not used because it requires the collection of several variables (expired air sample, hemoglobin, arterial oxygen saturation [Sao\textsubscript{2}], central venous oxygen saturation [Svo\textsubscript{2}]).

**Clinical Indices of Hypoperfusion**

General indices of hypoperfusion include a MAP less than 60 mm Hg, oliguria (urine output less than 0.5 mL/kg/hour), altered mental status, delayed capillary refill, and cool skin.\textsuperscript{9,30,31} Other measures include oxyhemoglobin saturation and serum lactate concentration.

The oxyhemoglobin saturation of venous blood drawn from a central vein (Scvo\textsubscript{2}) or the pulmonary artery (Svo\textsubscript{2}) is expressed as a percentage and is used as a surrogate marker for CO. The normal range for Svo\textsubscript{2} is 65%–75%. The Scvo\textsubscript{2} is drawn from a subclavian or
internal jugular CVC where the catheter tip terminates in the superior vena cava. As such, Scvo$_2$ is a reflection of oxygen extraction in the brain and upper body more than systemic oxygen extraction. The Scvo$_2$ drawn from a femoral CVC reflects only oxygen extraction from the lower body and does not account for cerebral oxygen extraction. Therefore, a femoral Scvo$_2$ cannot be used interchangeably with an Scvo$_2$ drawn from a thoracic CVC.$^{32,33}$

The Svo$_2$ value is drawn from a PAC and is a more accurate representation of systemic oxygen extraction because it represents the mixing of venous blood from the superior vena cava (upper extremity and cerebral oxygen extraction), inferior vena cava (lower extremity and abdominal organ oxygen extraction), and coronary sinus (myocardial oxygen extraction). Low Svo$_2$ is an indicator of a mismatch in the VO$_2$/DO$_2$ ratio, suggesting inadequate tissue perfusion. A low Svo$_2$ (less than 70%) is predictive of poor outcomes and has been associated with increased mortality.$^{32,34}$ Early reperfusion strategies targeting an Svo$_2$ greater than 70% in patients with septic shock showed improved survival.$^{15}$ However, more recent studies tested the value of using resuscitation protocols, targeting an Svo$_2$ greater than 70% in patients with septic shock, failed to show a survival benefit from this intervention.$^{17,18}$ Therefore, venous oxygen monitoring in septic shock should be used judiciously. In sepsis, microcirculatory shunting in the periphery can result in a lack of oxygen extraction. In addition, impaired mitochondrial oxygen use can result in normal or supranormal Svo$_2$, despite the presence of severe local tissue dysoxia.$^{35}$

Strategies to improve Svo$_2$ include fluid resuscitation, transfusion of packed red blood cells when the hemoglobin is less than 7 (for most critically ill patients) to increase oxygen supply, or administration of inotropic medications to improve DO$_2$.$^{36}$

Elevated blood lactate concentration (above 2 mmol/L) can also be used as a marker of tissue hypoperfusion. In the setting of dysoxia and shock, glycolysis transitions to anaerobic metabolism. Under these circumstances, lactate is the end product of glycolysis.$^{37-39}$ Elevated lactate concentrations may be the result of increased production (type
A), decreased clearance (type B), or both. Type A lactic acidosis occurs in the setting of decreased DO$_2$ to tissues. Type B lactic acidosis occurs in the setting of impaired lactate clearance from the liver or kidneys or has medication-related causes that impair oxidative phosphorylation (e.g., metformin, epinephrine, linezolid, propylene glycol, cocaine, or toxic alcohols). Serial lactate concentrations can be used as a resuscitation parameter, with the resolution of hyperlactatemia signifying the return of adequate systemic oxygenation. However, the utility of lactate as a resuscitation parameter is limited in severe liver dysfunction because of the major role (60%–70%) of the liver in the clearance of lactate. Severe liver dysfunction can lead to persistent or worsened lactate elevations in shock states.

### DIFFERENTIATION OF SHOCK STATES

Classically, shock can be classified into one of four categories: (1) hypovolemic, (2) obstructive, (3) cardiogenic, and (4) distributive. The various subtypes of shock are not mutually exclusive and can occur simultaneously. The estimated mortality increases with the cooccurrence of shock syndromes. Each of the shock categories is characterized by some mix of fluid loss, depressed CO, or maldistribution of oxygen because of the insufficiency of the peripheral uptake of oxygen (Table 10.3).

In a prospective, multicenter study of 1,679 intensive care unit patients, septic shock was the most common form of shock, accounting for greater than 60% of all patients with shock. Septic shock is characterized as a form of distributive shock, representing a complex interplay of cardiac and peripheral components to dysoxia. Septic shock will be discussed in detail in another chapter.

Other forms of shock become apparent on physical examination and focused assessment of hemodynamic parameters. For example, cardiogenic shock is likely in advanced heart failure or after a massive myocardial infarction. In a multinational study of patients hospitalized with acute coronary syndrome between 1999 and 2007, the incidence...
of cardiogenic shock was 4.6%, with an in-hospital mortality rate of 59.4%. Hypovolemic shock usually presents after acute loss of plasma (e.g., traumatic hemorrhage, surgical bleeding, gastrointestinal [GI] bleeding), burn injury, or sequestration of fluid within a body compartment (e.g., third spacing). Obstructive shock is apparent in impaired systolic contraction (e.g., pulmonary hypertension, massive pulmonary embolism [PE], or aortic dissection) or impaired diastolic filling (e.g., cardiac tamponade, tension pneumothorax, pericarditis).

Vasopressors and Inotropes

In most cases, vasopressors and inotropes are administered transiently to get patients through a critical period until the underlying etiology of shock is resolved. Vasopressors are initiated in patients who remain hypotensive despite adequate fluid resuscitation or in patients with severe hypotension during fluid resuscitation (see the Fluids, Electrolytes, and Nutrition section for further discussion of fluid components). Dynamic markers of resuscitation should be used to determine the efficacy of vasoactive agents; however, data are sparse regarding which resuscitation parameter is best. Resuscitation goals should depend on a confluence of patient-specific factors and will evolve throughout the care of a patient with shock. The clinician should use the patient-specific hemodynamic parameters when choosing a vasoactive agent (Table 10.4). Ultimately, the initiation and continuation of vasoactive agents are targeted to optimize the VO$_2$/DO$_2$ relationship. Of importance, it is critical to acknowledge that, for all vasopressors, doses and titration of therapy are unknown and based on collective experience. Dose suggestions provided in this chapter are taken from the primary literature.

The β$_1$-receptors are found primarily in the heart. Agonism at the β$_1$-receptor results in increased inotropy (contractility), increased chronotropy (heart heart), and increased dromotropy (conduction velocity). In general, agents with higher β$_1$-receptor affinity are used in patients with cardiogenic shock to improve contractility or in select patients with bradyarrhythmias to increase chronotropy. The most
common adverse effects of β₁-receptor stimulation are atrial and ventricular tachyarrhythmias. The β₂-receptors are located in the vascular smooth muscle, and agonism results in systemic vasodilation. The α₁-receptors are located throughout the body within the arteries, stomach, intestine, kidneys, and liver. The α₁-receptors are a primary mediator of arterial tone. Agonism at the α₁-receptors within the arteries results in vasoconstriction and an increase in SVR.

The dopamine 1 (D₁) receptors are located in the kidney, heart, and splanchnic vasculature. Agonism at the D₁-receptor results in vasodilation of the renal, coronary, and mesenteric beds.⁴⁸,⁴⁹

### Table 10.4 Vasoactive Pharmacology
The vasopressin (V1, V2) receptor, also called antidiuretic hormone, is an endogenous substance secreted from the hypothalamus in response to hypotension and high serum osmolality. The V1-receptors are located in the vascular smooth muscle; agonism at this receptor results in vasoconstriction. The V2-receptors are located within the renal collecting duct; V2 agonism results in water reabsorption from the distal tubules and collecting ducts of the nephron.50,51

Dopamine is an endogenous catecholamine with dose-dependent receptor activity at the D1-, β1-, and α1-receptors. Dopamine dosing breakpoints listed in this section are generalizations and should therefore not be considered absolute rules because patients can have variable responses to this medication according to their clinical scenario. Low doses (less than 3 mcg/kg/minute) cause vasodilation in the renal and mesenteric beds.52-54 However, studies have shown no renal protective effect from the use of low-dose dopamine in critically ill patients.52,55,56 Furthermore, the use of low-dose dopamine can have deleterious effects on respiratory drive, can induce or aggravate euthyroid sick syndrome, and can cause visceral ischemia.57 For this reason, this treatment modality is not recommended.16 Moderate doses (3–10 mcg/kg/minute) are thought to primarily cause β1-agonist activity and increased contractility and chronotropy. High doses (10–20 mcg/kg/minute) have mixed β1 and α1 activity resulting in increased SVR and contractility. Dopamine has many adverse effects including digital ischemia, tachyarrhythmias, and cardiac ischemia. In addition, there is evidence that dopamine can blunt hypoxic respiratory ventilator response, and it has been theorized that dopamine use in critically ill patients can delay liberation from mechanical ventilation.58-60

Dopamine
is no longer recommended as a first-line agent in the management of shock states as a result of a large, multicenter, randomized control trial comparing dopamine with norepinephrine in all-comers with shock. The study found no difference in mortality between the two groups at 28 days. However, dopamine use resulted in significantly higher rates of arrhythmic events (24.1% vs. 12.4%, p<0.001). In addition, in the subgroup analysis of patients with cardiogenic shock, dopamine administration resulted in a significantly higher rate of all-cause mortality.\textsuperscript{44}

Norepinephrine is an endogenous catecholamine with a strong affinity for the $\alpha_1$-receptor and a modest $\beta_1$-agonist effect. This results in increased SVR in patients with shock but has a moderate effect on cardiac contractility and chronotropy. Because norepinephrine has a reduced effect on chronotropy compared with dopamine, it is often used in patients with shock complicated by tachyarrhythmias. Prolonged exposure to norepinephrine can result in digital ischemia, visceral ischemia, and cardiotoxicity, causing myocardial chamber dilation, hyper-trophy, and ultimately systolic dysfunction.\textsuperscript{61,62}

Epinephrine is an endogenous catecholamine with agonist activity at the $\beta_1$-, $\beta_2$-, and $\alpha_1$-receptors. At low doses of epinephrine, $\beta_1$ and $\beta_2$ activity predominates, resulting in increased inotropy, chronotropy, and CO. At higher doses, epinephrine has a strong affinity for the $\alpha_1$-receptor, resulting in increased vascular tone and SVR.\textsuperscript{61,63,64} Low-dose epinephrine is commonly used after cardiac surgery for inotropic effects or for chronotropic effect in patients with bradycardia associated with high-grade atioventricular nodal block. Adverse effects of epinephrine include renal and splanchnic vasoconstriction, tachyarrhythmias, and digital ischemia. Prolonged infusions can result in myocardial dysfunction through myocyte apoptosis.\textsuperscript{48,49,65}

Phenylephrine is a pure $\alpha_1$-receptor agonist that increases MAP by increasing SVR. Phenylephrine is used as an adjunct to other vasopressors in refractory shock, to increase SVR in patients with severe aortic stenosis or to decrease LV outflow tract gradient in patients with hypertrophic obstructive cardiomyopathy. It is also used in patients with shock complicated by tachyarrhythmias. Adverse effects
of phenylephrine include baroreceptor-mediated reflex bradycardia, digital ischemia, visceral ischemia, and tissue necrosis with extravasation. See Figure 10.1 for selection of vasopressor therapy.

**Hypovolemic Shock**

Hypovolemic shock is primarily caused by hemorrhage and acute bleeding disorders. Occasionally, hypovolemic shock may be attributed to extensive volume loss (e.g., hemodialysis, diabetes insipidus) or extensive third spacing of intravascular volume. In the setting of bleeding, the principal concern is the circulatory system's inability to tolerate loss of blood.

Fluids account for around 50%–60% of total body weight in normal adults. Of this total, blood accounts for 60–66 mL/kg of body weight, representing 7%–12% of total body fluid. Acute blood loss activates rapid changes to maintain blood volume and perfusion. The initial response will facilitate capillary fill from the interstitium.
However, this movement of fluid will result in a deficit in the interstitial compartment. Progressively, activation of the renin-angiotensin-aldosterone system (RAAS) leads to sodium retention and replenishment of the interstitial fluid deficit. Activation of the RAAS may begin 8–12 hours after acute blood loss. Collectively, this compensatory response will maintain effective blood volume in the case of mild volume loss (less than 15% of blood volume) while resulting in adaptation in the form of SV, heart rate, and SVR. Volume loss in excess of 15% will require intravascular repletion. Blood loss is classified in four categories (Table 10.5).

Specific to hemorrhagic shock, clotting factors and platelets will be lost in addition to blood. It is estimated that 25% of all trauma patients will have an established coagulopathy on presentation to the emergency department.\(^7\)\(^1\) The loss of hemoglobin will compromise DO\(_2\). In addition, crystalloid resuscitation will lead to a dilutional coagulopathy, further compromising the ability to cease bleeding.

**Resuscitation Strategies for Hypovolemic Shock**

In hypovolemic shock, mortality is directly related to the extent of organ hypoperfusion. Therefore, prompt and deliberate repletion of intravascular fluids is key to survival and restoration of end-organ function.\(^7\)\(^2\) When possible, cessation of bleeding, or volume loss, is key.

The goals of resuscitation are to restore end-organ perfusion and improve DO\(_2\), beginning with the administration of intravenous fluids. After establishing venous access, the essential questions to guide resuscitation are as follows: (1) what type of fluid, (2) how much, (3) over what period, and (4) when to stop (i.e., what are therapeutic end points?). Patients with severe bleeding will not have compromised tissue oxygenation as long as an effective intravascular volume is maintained, even at low hemoglobin concentrations.\(^7\)\(^3\) Although there exists the debate of crystalloid versus colloid fluid choice, literature and many clinicians believe crystalloid resuscitation, in the form of lactated Ringer solution or normal saline, to be the primary means of
intravenous resuscitation. However, many clinicians prefer lactated Ringer when large-volume resuscitation is needed because of the development of hyperchloremic metabolic acidosis with large volumes of normal saline. Recognition of third-space losses has led to a “three-to-one” rule for resuscitation: 3 mL of crystalloid fluid for every 1 mL of blood loss.

Hypertonic saline has held promise among many clinicians as a resuscitative fluid. Potential benefits of hypertonic saline include its lesser distribution in the interstitium, oncotic effects to expand the vascular space, and portability because of the lesser amount of fluid needed to exert the same therapeutic benefit as isotonic fluids (normal saline or lactated Ringer). However, there is a lack of convincing data to date that shows the superiority of hypertonic saline.

There has existed a long-standing debate regarding the utility of colloidal fluids for resuscitation. Commonly reported colloidal therapies include albumin, hetastarch, and dextran. The primary purported benefit of colloids is their ability to be retained in the vascular compartment to a greater degree than crystalloids. This would mainly be because of their greater molecular weight. However, clinical trials have no found no benefit of one fluid over another.

Blood transfusions are indicated when the estimated blood loss exceeds 30%. However, estimating blood loss in the clinical setting is exceedingly difficult, and the decision to transfuse blood products is largely empirical. In practice, many clinicians transfuse blood products if the patient is hypotensive despite receiving 2 L of crystalloid fluid in the setting of an acute bleed. Practice guidelines recommend blood transfusion for a hemoglobin of 6–8 g/dL in critically ill patients. A randomized controlled trial of a restrictive transfusion strategy (hemoglobin 7–9 g/dL) compared with a conventional transfusion strategy (hemoglobin 10–12 g/dL) showed similar survival outcomes (19% vs. 23%, p=0.11), and mortality during hospitalization was significantly lower in the conservative transfusion arm (22% vs. 28%, p=0.05). A conservative transfusion strategy (hemoglobin 7–9 g/dL) has since become a standard of care in many intensive care units. Mortality during hospitalization was significantly lower in the
conservative transfusion arm (22% vs. 28%, p=0.05). In the setting of GI hemorrhage, a conservative transfusion strategy (hemoglobin less than 7 g/dL) compared with a liberal transfusion strategy (hemoglobin less than 9 g/dL) was associated with reduced rates of further bleeding (10% vs. 16%, p=0.01), fewer adverse effects (40% vs. 48%, p=0.02), and improved survival at 6 weeks (95% vs. 91%, hazard ratio 0.55 [95% confidence interval, 0.33–0.92; p=0.02]). Both studies support the notion that maintaining a hemoglobin in excess of 10 g/dL, without the necessity of improving DO$_2$, is largely unnecessary and may be harmful. Transfusion of blood products is not innocuous and carries the risk of viral transmission (e.g., HIV, hepatitis). Other adverse effects related to transfusions include electrolyte abnormalities, transfusion-related reactions, and the concern for immunosuppression.

Currently, the timing and intensity of resuscitation in the patient with hypovolemic shock is largely unanswered. Although it may seem
intuitive to initiate prompt and aggressive resuscitation, literature from the trauma setting suggests otherwise.\textsuperscript{84} In a prospective study of 598 adult patients with penetrating torso trauma and an SBP less than 90 mm Hg, delayed resuscitation until operative intervention was associated with an improved survival and discharge from the hospital alive (70\% vs. 62\%, p=0.04). Urban location, time to hospital transfer, and time to operative intervention are factors that may challenge the external validity of the study findings. Nevertheless, there is a lack of evidence in other clinical scenarios of hypovolemic shock that warrant further study. Concerns with aggressive resuscitation include the risk of worsening bleeding injury through increased velocity through the bleeding diathesis, worsening coagulopathy, and oxidative injury.

\textbf{COAGULOPATHY}

The incidence of coagulopathy after acute hemorrhage is associated with increased mortality and acute lung injury, multiple organ failure, and infections.\textsuperscript{85} In the wake of an acute hemorrhage, a combination of hypothermia, acidosis, and coagulopathy contribute to a maladaptive hemostatic response, further perpetuating the bleeding episode.\textsuperscript{86-88} Hypothermia is of serious consequence in the setting of hypovolemic shock because oxygen is not as readily uncoupled from hemoglobin to facilitate $O_2$ delivery as in the normothermic patient. Hypothermia also potentiates coagulopathy by inhibiting full activation of the clotting cascade.\textsuperscript{87,89} Passive and active warming methods to establish a core body temperature greater than 34°C are essential to reestablishing normal physiology and promoting hemostasis. In addition, prompt correction of acidosis to a pH greater than 7.20, through preload resuscitation, and coagulopathy, through blood product replacement, are essential to reversal of the triad. A typical approach to blood product replacement has been transfusion of packed red blood cells, fresh frozen plasma, cryoprecipitate, and platelets in a 1:1:1:1 ratio.\textsuperscript{90}

Systemic therapies to establish hemostasis in the patient with bleeding have been studied and reported. Recombinant activated factor VIIa (rFVIIa) works by activating the extrinsic pathway of the
coagulation cascade by interacting with tissue factor to activate factor X to factor Xa and factor IX to factor IXa. Preliminary case reports and case reports have suggested that administering rFVIIa improved clinical outcomes. However, a multicenter, randomized, controlled trial of rFVIIa in trauma patients was terminated early because of futility in the primary end point of mortality, despite showing a reduction in transfusion of packed red blood cells. Database reviews report an increased incidence of venous and arterial thromboembolic events with off-label rFVIIa use. Currently, there is no consensus on how rFVIIa should be used for the treatment of acute bleeding and hypovolemic shock.

Four different forms of prothrombin complex concentrates (PCCs) are available in the United States (Table 10.6). Of the different types of PCCs, only FEIBA (factor eight inhibitor bypassing inhibitor activity) possesses activated clotting factors. Kcentra is the only PCC to be approved for the indication of reversal of warfarin-related bleeding. All other PCC products are approved for hemophilia-related bleeding disorders. Extrapolating the use of PCCs for the treatment of acute bleeding disorders not related to the approved indications is experimental, and thoughtful consideration should be given to pharmacology, time to administration in the acute setting, and potential harms.

Tranexamic acid is an antifibrinolytic agent that has its pharmacodynamic effect through binding plasminogen to prevent the dissolution of a fibrin clot. Tranexamic acid was studied in trauma patients with hypovolemic shock caused by acute bleeding in a multicenter, randomized, placebo-controlled trial that showed improvement in 28-day mortality and mortality attributable to bleeding. In a subsequent analysis, the greatest benefit to the administration of tranexamic acid was noted when administered within the first 3 hours of injury. Tranexamic acid and α-aminocaproic acid have been studied for use in other settings, but with limited evidence.

---

**OBSTRUCTIVE SHOCK**
Obstructive shock is defined as the physical obstruction of the great vessels (pulmonary artery and aorta) or the heart itself. Therefore, obstructive shock is further broken into two distinct pathophysiologic mechanisms: impairment in diastolic filling (tension pneumothorax, cardiac tamponade, or constrictive pericarditis) and excessive afterload (severe pulmonary arterial hypertension, PE).

Cardiac tamponade occurs secondary to fluid accumulation within the intrapericardial space, resulting in alteration in the cardiac pressure-volume relationship, where the intrapericardial pressure exceeds that of the intracardiac pressure. This leads to diastolic collapse of the right atrial and ventricular free walls during expiration, a reduction in venous return, a subsequent reduction in CO, and ultimately shock. The emergency drainage of pericardial effusions is typically reserved for patients with RV collapse, hemodynamic instability (SBP less than 110 mm Hg), and the presence of pulsus paradoxus (greater than a 10-mm Hg drop in SBP during inspiration). Pericardiocentesis can be performed under fluoroscopy in the cardiac catheterization laboratory, drained under echocardiography at the bedside, or surgically drained. The creation of a surgical pericardial window is typically reserved for the management of recurrent effusions. Given the RV dependence on preload, initial management strategies may also include the judicious administration of intravenous fluids to patients with hemodynamic instability. However, fluid administration is only transiently beneficial, and a definitive strategy is required in patients with signs of impending collapse. Mechanical ventilation should be initiated with caution in patients with tamponade physiology caused by increased intrathoracic pressure, which can further decrease diastolic filling and may result in hemodynamic collapse.

Tension pneumothorax is typically caused by blunt thoracic trauma. It results in the progressive accumulation of air within the pleural space and displacement of the mediastinum. Mediastinal displacement can obstruct venous return, resulting in shock. Treatment requires immediate tube thoracostomy or needle decompression. Similar to tamponade, positive pressure ventilation can exacerbate
pneumothorax; therefore, pneumothorax should be treated before intubation.

Pulmonary embolism refers to the thrombotic occlusion of the pulmonary artery. The clinical presentation of PE can be heterogeneous, making diagnosis and the initiation of prompt treatment a challenge. Pulmonary embolism is a common etiology of obstructive shock caused by a severe increase in RV afterload resulting in RV overload (Table 10.7). Typically, the RV pumps blood into the low pressure pulmonary artery. However, in an acute PE, the RV must overcome a mechanical obstruction in addition to an acute rise in pulmonary arterial pressure secondary to hypoxic vasoconstriction. This results in RV overload and RV dilation, derangement of the Frank-Starling pressure-volume relationship, RV hypokinesis, intraventricular septal deviation toward the LV, reduction in LV size and preload, and reduction in systemic CO. The ensuing systemic hypotension and shock results in a decreased right coronary artery perfusion, RV ischemia and infarction, reduction in RV contractility, and further decrease in RV CO.

### Box 10.1. Contraindications for the Use of Fibrinolysis in Pulmonary Embolism

**Absolute Contraindications**

- Any prior intracranial hemorrhage
• Known structural cerebrovascular disease
• Known malignant intracranial neoplasm
• Ischemic stroke within the past 3 months
• Suspected aortic dissection
• Active bleeding or bleeding diathesis
• Recent surgery on the brain or spinal canal
• Recent significant closed-head or facial trauma with radiographic evidence of bony fracture or brain injury

Relative Contraindications
• Age > 75 years
• Current use of anticoagulation
• Pregnancy
• Noncompressible vascular punctures
• Traumatic or prolonged cardiopulmonary resuscitation (> 10 minutes)
• Recent internal bleeding (within 2–4 weeks)
• History of chronic, severe, and poorly controlled hypertension
• Severe uncontrolled hypertension on presentation (SBP > 180 mm Hg or DBP > 110 mm Hg)
• Dementia
• Remote (> 3 months) ischemic stroke
• Major surgery within 3 weeks

The initial management strategy for the management of a hemodynamically significant PE includes the judicious administration of fluids to maintain RV preload and CO; thrombolytic medications, when
indicated; and anticoagulants (Box 10.1). Close monitoring of these patients must be used to ensure that over-resuscitation does not worsen RV dilation and contractility. (See chapter 23, “Prevention and Treatment of Venous Thromboembolism,” for additional information.)

DISTRIBUTIVE SHOCK

Distributive shock is best characterized as an acute failure of the capacitance vessels, leading to a loss in perfusion and \( \text{DO}_2 \) to end organs. Most commonly, this occurs in the setting of acute infection and is called septic shock. Septic shock stems from an infection that leads to an imbalance in proinflammatory and anti-inflammatory cytokines, which also contributes to disorders of the coagulation system and the microcirculation. Septic shock will be described in detail in chapter 15, “Severe Sepsis and Septic Shock.”

Anaphylactic shock is the most feared complication of allergic reactions. Patients with eczema, asthma, and allergic rhinitis are at greatest risk of having anaphylactic reactions. Primarily because of the release of inflammatory cytokines from mast cells and basophils in response to antigen exposure, a multisystem organ failure rapidly develops, leading to hives, flushing, diarrhea, stridor, angioedema, and hypotension. Antigens can include a variety of exposures, not limited to bee stings, eggs, nuts, and medications (e.g., \( \beta \)-lactams, aspirin, protamine). Antigen binding to immunoglobulin E (IgE) triggers a series of pathophysiologic processes resulting in bronchial smooth muscle contraction, vasodilation, and ventricular depression. Epinephrine administered intramuscularly is the primary treatment for an anaphylactic episode (0.01 mg/kg for children weighing less than 10 kg; 0.15 mg for children weighing 10–25 kg; 0.30 mg for children and adults weighing more than 25 kg). Although intuitive, evidence does not support the administration of antihistamines (histamine-1 and histamine-2 antagonists) for the treatment of anaphylactic reactions. Corticosteroids have no benefit in the immediate treatment, but they may mitigate the risk of a biphasic anaphylactic reaction.\(^{96,97}\)
CONCLUSION

Shock represents a heterogeneous collection of syndromes. Effective treatment requires a thorough assessment of patient-specific factors, an understanding of pharmacologic agents, and a time-sensitive application of therapies.

LEARNING OBJECTIVES

1. Describe a strategy to deliver appropriate initial antibiotic regimen employing knowledge of local epidemiology, antibiotic resistance prediction tools and clinical decision support systems.

2. Identify possible pharmacokinetic abnormalities in critically ill patients and provide a method to optimize drug dosing given the specific alteration.

3. Describe an approach to antibiotic de-escalation based on negative and positive results of microbiological studies.

4. Provide justification for implementation of antimicrobial stewardship programs in the intensive care unit.

ABBREVIATIONS IN THIS CHAPTER

ARC  Augmented renal clearance
ASP  Antimicrobial stewardship program
GNB  Gram-negative bacilli
HAP  Hospital-acquired pneumonia
INTRODUCTION

Appropriate use of antimicrobials is an important concept that is pertinent to virtually every clinician. This practice is intended to ensure the optimal selection, dose, and duration of antimicrobials leading to the best clinical outcome for the treatment or prevention of infection while producing the fewest possible adverse effects and the lowest risk of subsequent resistance.\textsuperscript{1,2} Although progress in achieving these goals has been realized through the implementation of stewardship programs,\textsuperscript{3} there is considerable room for improvement.\textsuperscript{4,5} Given the critical nature of patients admitted to the intensive care unit (ICU) setting, optimization of antimicrobial practices in the ICU is of paramount importance.\textsuperscript{3,5-7}

Appropriate Antimicrobial Selection

Administering appropriate initial antibiotic therapy is the cornerstone of the management of septic shock as well as of any serious infection requiring ICU care. Appropriate initial antibiotic therapy is defined as an antimicrobial regimen that has in vitro activity against the isolated organism(s) responsible for the infection, whereas inappropriate initial antibiotic therapy is defined as an initial regimen showing a lack of in vitro activity against the causative pathogen(s).\textsuperscript{8} The administration of inappropriate initial antibiotic therapy can lead to treatment failures and adverse outcomes.\textsuperscript{9,10} It has been shown that patients with septic shock attributed to bacterial infection who received inappropriate initial
antimicrobial therapy have an increased risk of mortality relative to patients treated with appropriate initial therapy (odds ratios [ORs] of 1.80–6.86).\textsuperscript{11-15} Similar associations between the administration of inappropriate initial antimicrobial therapy and greater mortality have been shown for Candida bloodstream infections.\textsuperscript{16-18} Moreover, the importance of treating pathogens associated with serious infection was further emphasized by a retrospective cohort analysis of patients with bloodstream infection complicated by severe sepsis and septic shock.\textsuperscript{19} For the entire cohort, the number needed to treat (NNT) with appropriate initial antimicrobial therapy to prevent one patient death was 4.0 (95% confidence interval [CI], 3.7–4.3). The prevalence-adjusted pathogen-specific NNT with appropriate initial antimicrobial therapy to prevent one patient death was lowest for multidrug-resistant (MDR) bacteria (NNT = 20), followed by Candida spp. (NNT = 34), methicillin-resistant Staphylococcus aureus (MRSA; NNT = 38), Pseudomonas aeruginosa (NNT = 38), Escherichia coli (NNT = 40), and methicillin-susceptible S. aureus (NNT = 47).\textsuperscript{19}

The importance of selecting appropriate initial antimicrobial therapy has been emphasized in the Surviving Sepsis Guidelines.\textsuperscript{20} The guidelines recommend that initial empirical anti-infective therapy include one or more drugs with activity against all likely pathogens (bacterial and/or fungal or viral) and that the antibiotics penetrate in adequate concentrations into the tissues presumed to be the source of sepsis (grade 1B).\textsuperscript{20} This guideline urges clinicians to use the patient’s history, including drug intolerances, recent receipt of antibiotics, underlying disease, clinical syndrome, and susceptibility patterns of pathogens in the community and hospital that have been previously documented to colonize or infect the patient when making decisions regarding initial antimicrobial regimen selection. However, given the severity of illness for ICU patients with severe sepsis and septic shock, erring on the side of initial overtreatment may be preferable to administering an inappropriate initial antibiotic regimen. Balancing these competing interests is at the core of antimicrobial stewardship in the ICU, and methods for refining this balance are subsequently described.
Identifying Patients at Risk of MDR Pathogens
Knowledge of patient risk factors associated with the presence of infection caused by antibiotic-resistant pathogens should be a routine part of initial antibiotic decision-making (Box 11.1). For example, in patients presenting from the community with pneumonia, risk factors for antibiotic-resistant pathogens include prior hospitalization, immunosuppression, previous antibiotic use, use of gastric acid-suppressive therapy, tube feeding, and non-ambulatory status. Severity of illness is another risk factor that has been associated with a higher frequency of MDR pathogens in patients presenting to the hospital with pneumonia. Scoring systems that assign points to individual patients on the basis of disease severity as well as other potential risk factors for MDR pathogens is an approach that can be used to improve the rates of appropriate initial therapy without excessive use of broad-spectrum antibiotic therapy. A retrospective study examined patients admitted with pneumonia and found four variables predictive of antibiotic-resistant pneumonia: recent hospitalization, nursing home residence, hemodialysis, and ICU admission. A scoring system assigning 4, 3, 2, and 1 points, respectively, for each variable had moderate predictive power for segregating those with and without resistant bacteria. Among patients with fewer than 3 points, the prevalence of resistant pathogens was less than 20% compared with 55% and more than 75% in individuals with scores of 3–5 and more than 5 points, respectively. The same scoring system was validated in an independent population showing that it performed better at identifying patients infected with antibiotic-resistant bacteria than simply using the definition of health care–associated pneumonia (HCAP). The risk score was statistically greater among patients with antibiotic-resistant infections (median score, 4 vs. 1; p<0.001). A recent meta-analysis also found that the current definition used for HCAP did not accurately identify infections attributed to antibiotic-resistant pathogens, providing further support for the use of more specific criteria to make this clinically important determination. It is unclear, however, whether clinicians can effectively apply scoring systems prospectively in an effort to target the
administration of broad-spectrum antibiotics in patients at greatest risk of infection with antibiotic-resistant infections. This has served as the impetus for developing clinical decision support systems to facilitate such decision-making at the patient’s bedside.

**Box 11.1. Risk Factors Associated with Antimicrobial Resistance**

- Prior antimicrobial exposure
- Prolonged antimicrobial therapy
- Subtherapeutic antimicrobial dosing
- Previous hospitalization
- Prolonged hospital stay
- Intensive care unit admission or increasing severity of illness
- Recent surgery
- Insertion of an invasive device(s) (e.g., urinary catheter, central venous catheter, endotracheal tube)
- Admission from a long-term care facility
- Poor functional status before admission
- Chronic comorbidities (heart, lung, liver, or kidney disease; diabetes, immunocompromised)

**Clinical Decision Support Systems**

Clinical decision support systems represent a method of coupling patient-specific risk factors for antibiotic-resistant bacteria that is warehoused in local data repositories with historical culture and
susceptibility reports to facilitate bedside decision-making. Use of such data at the point of antimicrobial prescription has resulted in a significant reduction in the proportion of patients prescribed broad-spectrum antibiotics after adjustment for risk factors including APACHE II (Acute Physiology and Chronic Health Evaluation II) score, suspected infection, positive microbiology, intubation, and length of stay. In addition, the decision support tool was associated with a 10.5% reduction in both total antibiotic use and use of the highest-volume broad-spectrum antibiotics. Similarly, an automated decision support system with real-time access to patients’ prior antibiotic exposures and microbiologic results, including those from prior hospitalizations at outside institutions, has shown that the use of inappropriate initial therapy can be reduced by almost 50% and that access to these data assist in the performance of timely de-escalation. Other benefits derived from the use of computerized systems include improvements in the efficiency and costs of existing stewardship programs, improvements in clinicians’ knowledge regarding the treatment of infectious diseases, and improvements in pathogen prediction. These data suggest that an opportunity exists to use hospital informatics systems to improve the identification of patients at risk of, or infected with, antibiotic-resistant bacteria in order to prescribe more appropriate initial therapy.

**Timing of Antibiotic Administration**

In addition to selecting an appropriate initial antimicrobial regimen, the timing of antibiotic administration relative to the onset of symptoms or culture collection is an essential element in determining the outcome of critically ill patients with infection. In a prospective study of patients with ventilator-associated pneumonia (VAP), the administration of appropriate initial therapy that was delayed 24 hours or more after the patient met the diagnostic criteria was identified as a risk factor independently associated with hospital mortality by logistic regression analysis (adjusted OR 7.68; 95% CI, 4.50–13.09; p<0.001). A retrospective study of 2,154 patients with septic shock who received effective antimicrobial therapy in conjunction with the onset of recurrent
or persistent hypotension found a strong relationship between the delay in treatment and in-hospital mortality (adjusted OR for increased mortality 1.119 [per hour delay], 95% CI, 1.103–1.136, p<0.0001). Administration of an antimicrobial regimen determined to be effective for the isolated or suspected pathogens within the first hour of documented hypotension was associated with a survival rate of 79.9%. Each hour of delay in antimicrobial administration over the ensuing 6 hours was associated with an average decrease in survival of 7.6% per hour.

A meta-analysis of randomized and observational studies evaluating the impact of goal-directed bundles on the outcomes of patients with septic shock found that timely antibiotic administration was statistically more common among patients receiving protocolized management of septic shock than among those receiving non-protocolized care. One study in this meta-analysis was a prospective observational study that evaluated adult patients with severe sepsis from 77 ICUs. Using a propensity-adjusted multivariate analysis, the authors found that early broad-spectrum antibiotic treatment (treatment within 1 hour vs. no treatment within the first 6 hours of diagnosis) was associated with a significant reduction in hospital mortality (OR 0.67; 95% CI, 0.50–0.90; p=0.008). A retrospective analysis of a large data set collected prospectively from 165 ICUs in Europe, the United States, and South America found a statically significant increase in the probability of death associated with the number of hours of delay for first antibiotic administration. Hospital mortality increased from 24.6% to 33.1% as the time to antibiotic administration increased from 0 to greater than 6 hours where 0–1 hour was the referent group.

Timely administration of effective antibiotics appears to be an important element in determining the outcome of critically ill patients. Emergency departments and ICUs should ensure that processes are in place to obtain and deliver antibiotic therapy expeditiously once the order for such therapy is received from the treating physicians.

**Adequate Dosing of Antimicrobials**

In addition to delivering timely appropriate antibiotic regimens,
adequate drug concentrations at the site of infection are needed to optimize clinical outcomes. It is widely accepted that time-dependent antimicrobials show optimal bacterial killing when the duration of time of the free drug concentration exceeds the pathogen minimum inhibitory concentration ($T_{FREE}/MIC$). For example, a $T_{FREE}/MIC$ of 100% of the dosage interval should be a theoretical target for β-lactams and carbapenems. However, further improvement in the efficacy of β-lactams has been observed when concentrations 4- to 5-fold greater than the MIC are achieved for prolonged periods during each dosing interval. An example of the need for proper antibiotic dosing and drug exposure at the site of infection in critically ill patients was shown in a multi-center trial designed to evaluate whether antibiotic concentrations affect patient outcomes. Of the 248 patients treated with β-lactams for infection, 16% did not achieve a $T_{FREE}/MIC$ greater than 1 at 50% of the dosing interval, and these patients were 32% less likely to have a positive clinical outcome. A positive clinical outcome was associated with a $T_{FREE}/MIC$ ratio greater than 1 at both 50% and 100% of the dosing intervals (OR 1.02 and 1.56, respectively; p<0.03). These data suggest that many critically ill patients have adverse outcomes as a result of inadequate antibiotic exposure.

Several other studies have shown that the doses of antibiotics administered to critically ill patients may need to be augmented despite the clinician’s having selected an appropriate initial regimen. Meta-analyses of tigecycline for the treatment of nosocomial infections have shown an increased mortality versus comparator agents, particularly in VAP caused by gram-negative pathogens. A randomized trial of patients with hospital-acquired pneumonia (HAP) found that tigecycline, with or without ceftazidime, had inferior cure rates to imipenem/cilastatin with or without vancomycin across all pathogens (cure rates for VAP were 48% vs. 70%). Researchers hypothesized that the tigecycline dose (75 mg every 12 hours) was too low to achieve high enough concentrations above the MICs of pathogens, which prompted a higher-dose study (100 mg every 12 hours) compared with imipenem/cilastatin. In this study, 85% of the patients in the high-dose tigecycline group achieved clinical cure compared with
75% in the imipenem group, suggesting that underdosing of tigecycline has contributed to the poor outcomes observed in prior trials, especially in VAP. Similarly, ceftobiprole, a cephalosporin with activity against MRSA and a gram-negative spectrum similar to that of ceftazidime or cefepime, was compared with linezolid and ceftazidime in patients with HAP/VAP. \(^{48}\) Even though similar cure rates in HAP were achieved, ceftobiprole was inferior to linezolid and ceftazidime in patients with VAP (cure rates from intention to treat analysis: 23.1% vs. 36.8%). This finding was thought to be largely because of the under-dosing of ceftobiprole in critically ill patients. The concern for underdosing in critically ill patients has led to a doubling of the dose of ceftolozane/tazobactam in the ongoing clinical registration trials of HAP/VAP compared with the dosing regimens used in the intra-abdominal and urinary tract infection registration trials.\(^{49,50}\)

**Pharmacokinetic Considerations**

Many factors influence the pharmacokinetics of antimicrobials in critically ill patients and may contribute to the underdosing of antimicrobials. Hypoalbuminemia, large-volume crystalloid administration, large pleural effusions or abdominal ascites, catecholamines, and renal replacement therapies (see Table 11.1) can all significantly alter infection-site concentrations of administered antibiotics.\(^{51,52}\) One factor worth specific mention is augmented renal clearance (ARC).

Augmented renal clearance is defined as an 8-hour creatinine clearance (CrCl) of 130 mL/minute/1.73 m\(^2\) or more. At least one recent study suggests that more than 65% of ICU patients have an ARC on at least one occasion during the first 7 days of their critical illness.\(^{53}\) Augmented renal clearance has been linked with subtherapeutic \(\beta\)-lactam\(^{54}\) and glycopeptide concentrations\(^{55}\) as well as increased therapeutic failures in patients receiving antimicrobial therapy, resulting in adverse patient outcomes.\(^{56}\) In a study comparing 10 days of imipenem/cilastatin with 7 days of doripenem for VAP caused by gram-negative bacilli (GNB), the largest difference in clinical cure rates, which favored the longer-duration imipenem/cilastatin
regimen, was in the subgroup of patients with a CrCl greater than 150 mL/minute/1.73 m$^2$. This finding suggests that shorter therapy durations among patients with ARC, and thus lower circulating antibiotic concentrations, can contribute to excess mortality. One group of investigators has developed a scoring system to identify patients at high risk of ARC because of the following factors: age 50 years or younger (6 points), trauma (3 points), and Sequential Organ Failure Assessment (SOFA) score of 4 or less (1 point). Higher summated scores were significantly associated with ARC. A subsequent study found that the ARC score was 100% sensitive and 71.4% specific for detecting ARC.

**Prolonged Infusions of Antibiotics**

To adjust for altered pharmacokinetic parameters in critically ill patients and achieve greater Time$>$MIC for β-lactams, alternative antimicrobial dosing and administration strategies have been studied. The most common strategy studied has been prolonged or continuous infusions of time-dependent antimicrobials including β-lactams, carbapenems, and vancomycin. Although observational studies have shown better clinical cure rates with prolonged or continuous infusion of β-lactams, two meta-analyses have failed to confirm these findings.$^{60,61}$ However, a meta-analysis that included vancomycin and linezolid$^{62}$ and another focusing specifically on piperacillin/tazobactam or carbapenems$^{63}$ found improved clinical outcomes, including lower mortality, when antibiotics were administered by prolonged or continuous infusion compared with bolus injections. Of note, many of the trials included in these analyses were retrospective in design or of limited power because of small sample size. It is also important to recognize that prolonged infusion of antibiotics will not compensate for poor initial drug selection, inferior drug characteristics, or underdosing of these agents in critically ill patients, as suggested by the tigecycline experience$^{43-45}$ and the ceftobiprole study of HAP/VAP.$^{48}$ The largest (n=432) randomized, multicenter trial conducted to date of continuous β-lactam infusion compared with intermittent infusion in critically ill patients with severe
sepsis found no difference in alive ICU-free days, 90-day survival, or clinical cure 14 days after antibiotic cessation.\(^{64}\)

**Therapeutic Drug Monitoring**
The best method to ensure adequate drug concentrations in the serum is therapeutic drug monitoring (TDM).\(^{65,66}\) However, the use of TDM for antibiotics other than vancomycin, aminoglycosides, and voriconazole has not become a routine or standard practice in most ICUs. Studies have shown the ability of TDM to identify the need for antibiotic dosing adjustments in the setting normal kidney function,\(^ {67}\) fluctuating kidney function,\(^ {68}\) and in the patients with acute kidney injury requiring
continuous renal replacement therapy. Unfortunately, large variations currently exist in the type of β-lactams tested, the patients selected for TDM, drug assay methodologies, pharmacokinetic/pharmacodynamic targets, and dose adjustment strategies used in critically ill patients, and further studies are thus needed.

Rapid Microbiologic Diagnostics

Conventional microbiologic procedures typically require several days for isolation, identification, and antimicrobial susceptibility testing of isolated bacteria from clinical samples including blood, respiratory tract, urine, and sterile site specimens. Because of the time-consuming nature of these procedures, identification of resistant bacteria is often delayed, resulting in the administration of inappropriate initial antibiotic therapy. Rapid diagnostic methods offer the capability of influencing early antibiotic decision-making in order to allow for administration of appropriate therapy for antibiotic-resistant bacteria that is more prompt, as well as minimization of unnecessary use of broad-spectrum agents. Several molecular diagnostic platforms for the rapid diagnosis of bacterial species and their accompanying resistance genes have been introduced and evaluated, including the LightCycler SeptiFast Test (Roche, Basel, Switzerland), peptide nucleic acid fluorescence in situ hybridization (PNA-FISH) (AdvanDx, Woburn, MA), matrix-assisted laser desorptionionization time of flight mass spectrometry (MALDITOF MS) (VITEK MS; bioMérieux, Inc., Durham, NC), and DNA-based microarray platforms (Prove-it sepsis assay [Mobidiag, Keilaranta, Finland] and the Verigene Gram-Positive Blood Culture assay [Nanosphere, North-brook, IL]). In addition, automated microscopy methods such as the ID/AST system (Accelerate Diagnostics, Tucson, AZ) are in development using both genomic and phenotypic technologies to provide pathogen identification and antimicrobial susceptibilities in a rapid manner.

The potential impact of rapid diagnostic technology in the clinical setting has been reported. A quasi-experimental study evaluated MALDI-TOF MS in conjunction with an antimicrobial stewardship team intervention in patients with bloodstream infections. In this study, the
antimicrobial stewardship team provided antibiotic recommendations after receiving real-time notification following blood culture Gram stain, organism identification, and antimicrobial susceptibilities using conventional microbiology methods in the before-period and MALDITOF MS in the after-period. Use of MALDI-TOF MS significantly decreased time to organism identification and improved time to effective antibiotic therapy as well as optimal directed antibiotic therapy. Mortality, length of ICU stay, and recurrent bacteremia were significantly lower during the intervention period. Similarly, use of the PCR-based GeneXpert MRSA/SA diagnostic platform (Cepheid, Sunnyvale, CA) showed that for methicillin-susceptible S. aureus bacteremia, the mean time to initiation of appropriate therapy was reduced from 49.8 hours to 5.2 hours, and the duration of unnecessary MRSA drug therapy was reduced by 61 hours per patient. It is expected that as rapid diagnostics further develop, their impact on antimicrobial stewardship will increase, given their enhanced ability to direct early appropriate treatment and avoid unnecessary antibiotic exposure.

De-escalation of Empirical Antibiotic Regimen
When risk factors for antibiotic resistance are identified in patients with a serious infection, broad-spectrum antimicrobials should be prescribed. This approach usually requires initial combination antimicrobial treatment targeting nonfermenting GNB (P. aeruginosa, Acinetobacter spp., Stenotrophomonas maltophilia) and MRSA. However, depending on clinical presentation, patient risk factors, and local epidemiology, other pathogens such as Candida spp. and Clostridium difficile, especially when diarrhea is present, may also need to be covered. Once the microbiologic results are available and the patient’s clinical response is observed, the antibiotic regimen can de-escalated or narrowed depending the susceptibilities of the identified pathogen(s). De-escalation (see Figure 11.1) usually refers to a reduction in the spectrum of administered antibiotics through the discontinuation of antibiotics providing activity against pathogens that were not identified, discontinuation of antibiotics with similar activity, or
switching to an agent with a narrower spectrum. Through the practice of de-escalation, clinicians limit unnecessary antimicrobial exposure in order to curtail the emergence of resistance.

Intensivists should expect that a de-escalation approach to antimicrobial therapy in critically ill patients will optimize patient outcomes. A prospective observational study evaluated the clinical outcomes of a de-escalation strategy compared with those of standard practices in 628 patients with severe sepsis or septic shock at ICU admission who were treated empirically with broad-spectrum antibiotics. Antibiotic therapy was guided by written protocols advocating for de-escalation therapy once the microbiological results became available (day of culture results), although this decision was ultimately the responsibility of the physician in charge of the patient. By multivariate analysis, factors independently associated with in-hospital mortality were septic shock, SOFA score on the day of culture results, and inappropriate empirical antimicrobial therapy, whereas de-escalation of antimicrobial therapy was found to be an independent variable associated with significantly improved odds of hospital survival. In addition, among patients receiving appropriate therapy, the only factor independently associated with mortality was the SOFA score on the day of culture results, whereas de-escalation therapy was again found to be a protective factor. These investigators found that 57 of 628 patients (9.1%) received inappropriate empirical therapy and 246 of 628 patients (39.2%) had no change in their empirical antibiotic regimens, indicating further opportunity to improve their de-escalation practice.
Figure 11.1 De-escalation pathway. PCT = procalcitonin.

Strategies described in the literature that promote antimicrobial de-escalation in critically ill patients include protocol-driven de-escalation,
clinical pharmacist–led de-escalation, and infection-specific treatment pathways (VAP and skin and soft tissue infections). Each method has shown significantly shorter durations of antimicrobial treatment than a standard, physician-led approach.

**Biomarker Guidance of Antibiotic Therapy**
The biomarker procalcitonin is a precursor of calcitonin that is released rapidly into the bloodstream in the presence of an infection. Serial measurements of procalcitonin have been evaluated as a method to guide decisions regarding the duration of antimicrobial therapy. In a randomized trial, 101 patients with VAP were assigned to a de-escalation strategy as recommended by the American Thoracic Society/Infectious Diseases Society of America guidelines, with active education regarding those guidelines, versus a procalcitonin-dictated de-escalation protocol. At 72 hours into the treatment course, the discontinuation of antimicrobials was strongly encouraged if procalcitonin concentrations were less than 0.5 mcg/L or if procalcitonin concentrations had decreased by greater than 80%. When comparing these with treatment approaches, a 27% absolute reduction in the overall duration of antibiotics was achieved in the procalcitonin group compared with the group receiving guideline-driven therapy. Similar findings showing reduced antimicrobial use with a procalcitonin-directed approach to the duration of therapy have been observed in other studies. In addition, two meta-analyses suggest that procalcitonin guidance can be used to shorten the duration of antimicrobial therapy in the ICU setting.

However, not all experiences with procalcitonin-guided decision-making have shown reductions in duration of antibiotic exposure. A multicenter trial that enrolled 400 patients with suspected bacterial infection/sepsis found a similar number of antibiotic treatment days when comparing procalcitonin-guided antibiotic management with standard care. Perhaps the discrepancy in findings related to the duration of therapy associated with procalcitonin-guided antibiotic management in critically ill patients can be explained by the utility, or lack thereof, in procalcitonin’s ability to discriminate between the
various stages in the continuum of SIRS (systemic inflammatory response syndrome), sepsis, severe sepsis, and septic shock. Although higher procalcitonin concentrations suggest the presence of a systemic bacterial infection as opposed to a viral, fungal, or inflammatory etiology of sepsis, serum procalcitonin concentrations have not been shown to correlate with the severity of sepsis or with mortality and therefore should not be used to dictate the timing and appropriateness of de-escalation (or escalation) of antimicrobial therapy in patients with sepsis.

Fungal infections often present a considerable diagnostic challenge to clinicians, and the mere suspicion of these infections often leads to liberal and prolonged anti-fungal use. The serum markers, (1,3)-β-d-glucan, a fungal wall component and galactomannan Aspergillus antigen, have been studied in conjunction with standard culture techniques to quickly identify patients with invasive fungal infections and assist in clinician decision-making regarding continued antifungal therapy. Because of their high negative predictive value in the appropriate clinical setting, the most suitable use of these markers seems to be in excluding the presence of invasive fungal infections and de-escalating antifungal therapy. However, one study suggests that (1,3)-β-d-glucan is the most rapid method for identifying intra-abdominal candidiasis in order to provide timely therapy in such patients. In addition, an investigation that measured galactomannan concentrations in bronchoalveolar lavage (BAL) fluid obtained from ICU patients lends support to its use in the identification of Aspergillus and early treatment of pulmonary infection. Nonetheless, a more recent study showed only modest agreement between galactomannan in BAL fluid and validated clinical diagnostic criteria for invasive fungal disease. These markers of infection have the potential to enhance stewardship—primarily through de-escalation once a fungal infection has been excluded—and future clinical experience with these markers will determine whether this potential can be fully realized.

**Duration of Antibiotic Therapy**
For most critically ill patients, empirical antibiotic courses of 7–8
treatment days should suffice unless specific infections are identified such as bacteremia, fungemia, endocarditis, osteomyelitis, and others that would require longer treatment durations. The data supporting the use of shorter courses of antibiotic therapy are probably strongest for VAP, depending on clinical severity, rapidity of clinical improvement, and, most importantly, the underlying microbiology.\textsuperscript{98-100} The exceptions to shorter courses of antibiotic therapy in VAP are the difficult-to-treat pathogens like \textit{P. aeruginosa} and other nonfermenting GNB such as \textit{Acinetobacter} spp. that have a higher recurrence rate with shorter treatment regimens.\textsuperscript{101} At least one randomized trial has found a greater mortality among patients with \textit{P. aeruginosa} VAP receiving only 7 days of treatment.\textsuperscript{57} This study, which compared 7 days of doripenem (4-hour infusion) and 10 days of imipenem/cilastatin (1-hour infusion) in patients with microbiologically confirmed VAP, was halted before completion because of excessive higher 28-day mortality in the doripenem group. Longer treatment durations for nonfermenting GNB may be most important when antibiotic exposure in the lung is limited by host factors such as increased volume of drug distribution and ARC.

In summary, clinicians should be aware that 7–8 days of therapy should suffice for empirical antibiotic treatment in most ICU patients. However, even shorter courses of empirical therapy should be used when the presence of infection is excluded, and longer treatment regimens may be required when dealing with specific sources of infection (i.e., endocarditis) and certain pathogens, including \textit{P. aeruginosa}. It is most important to critically review all antibiotics on a daily basis to ensure that they are indeed necessary and, if so, that they are delivered in adequate concentrations.\textsuperscript{82}

**Formalized Antimicrobial Stewardship Programs**
 Hospitals are often seen as inflexible institutions when it comes to implementing practice changes. This has resulted in a call to have executive-level planning, local cooperation, sustained education, emphasis on de-escalation, and locally derived care bundles used singly or in combination in order to promote practice changes that are consistent with antimicrobial stewardship goals and aimed toward
decreasing antimicrobial resistance. Formally implemented antimicrobial stewardship programs (ASPs) have been associated not only with reduced infection rates but also significant cost savings associated with reductions in the defined daily doses of the antimicrobials targeted by the ASP. Antimicrobial stewardship programs have been shown to increase the appropriateness of therapy for serious infections such as CAP as well as to increase the number of infectious diseases consultations, which might also dramatically improve patient outcomes including mortality, hospital lengths of stay, and readmission rates by providing more precise antibiotic prescription. These attributes of ASPs account for why they are now recognized as mandatory components of hospital quality improvement efforts.

A meta-analysis of ASPs has solidified the benefits of these quality improvement initiatives. This meta-analysis found that ASPs could significantly result in less antimicrobial use and that these programs were associated with reductions in C. difficile infections and colonization or infection with aminoglycoside- or cephalosporin-resistant GNB, MRSA, and vancomycin-resistant Enterococcus faecalis. In addition, antibiotic prescribing practices for pneumonia made more effective because of the presence of an ASP were associated with a significant reduction in mortality, whereas practices aimed at decreasing excessive antibiotic prescribing were not associated with any significant increase in mortality. This meta-analysis supports the role of formalized ASPs not only to restrict the use of unnecessary antibiotics but also to ensure that antimicrobials are used in an effective manner to optimize patient outcomes.
CONCLUSION

Although antimicrobial therapy is often prescribed, clinicians should realize that these important therapeutic agents should be used wisely. Judicious use of antibiotics serves to combat the emergence of resistance, improve clinical outcomes, and decrease costs (Figure 11.2). The challenge to ICU clinicians is how to use these agents most effectively in order to maximize patient benefits while minimizing the emergence of resistance. Intensive care unit clinicians must be the leaders in ensuring that their institutions have robust and effective ASPs.¹⁰⁹

Pharmacokinetic and Pharmacodynamic Considerations for Antimicrobial Use in Critically Ill Patients

Douglas N. Fish, Pharm.D., FCCP, FCCM, BCPS-AQ ID

LEARNING OBJECTIVES

1. Describe basic principles of antimicrobial pharmacodynamics (PD) and the specific parameters used to describe the properties of time- and concentration-dependent drugs.

2. Discuss the cause and significance of potential pharmacokinetic (PK) alterations in critically ill patients, including changes in drug absorption, distribution, clearance, protein binding, and half-life.

3. Discuss general strategies for antimicrobial dosing and dose adjustments in critically ill patients.

4. Describe specific PK/PD goals for dosing of time-dependent antibiotics, concentration-dependent antibiotics, and antifungal agents.

5. Discuss clinical applications of PD principles that are currently being used or investigated for dose optimization of antimicrobials.

6. Describe potential limitations to applying PK/PD principles of
dose optimization in critically ill populations.

7. Given a critically ill patient requiring antimicrobial therapy, apply appropriate PK/PD principles to recommend an appropriate dosing regimen that incorporates consideration of potential PK alterations and desired PD targets.

**INTRODUCTION**

Antibiotic treatment of critically ill patients remains a significant challenge to clinicians worldwide because of high infection-related
mortality and morbidity rates. Patients are often admitted to the intensive care unit (ICU) for the treatment of community- or hospital-acquired infections, and many other patients require treatment for nosocomial infections acquired during their ICU stay. Although patients in ICUs represent only 8%–15% of hospital admissions in the United States, these patients have a disproportionately high rate of infectious complications and are exposed to very high rates of antimicrobial use. The importance of effective antimicrobial therapy is also underscored by the ever-increasing severity of illness of patients being admitted to the ICU. The importance of antimicrobial drugs in the modern management of critically ill patients with a variety of bacterial, fungal, and viral infections can scarcely be understated. However, despite the availability of improved diagnostic techniques and a wide variety of potent, highly effective antimicrobials, the appropriate treatment of infections in ICU patients remains a formidable challenge to the clinician.

Optimization of antimicrobial therapy remains a high priority in the management of critically ill patients. Antimicrobials are often selected primarily because of their spectrum of antimicrobial activity against presumed or documented pathogens. However, because of the high risk of severe morbidity and mortality associated with infections in critically ill patients, particular consideration must also be given to other pharmacologic properties. Optimization of antimicrobial therapy requires that drugs be dosed in a manner that maximizes their pharmacologic activity while minimizing the risk of adverse effects and toxicities. Special consideration must therefore be given to antimicrobial pharmacokinetic (PK) and pharmacodynamic (PD) properties; indeed, the optimization of antimicrobial dosing regimens is almost as important as the actual choice of drug with respect to achieving favorable patient outcomes while minimizing the risk of antimicrobial resistance.

An endless variety of physiological alterations may occur in critically ill patients, many of which have the ability to significantly affect the PK/PD properties of drugs used in this patient population. Pharmacokinetic changes often result from organ dysfunction, most importantly the kidneys and liver, but they may also be caused by
therapeutic interventions including volume resuscitation and renal replacement therapy. Knowledge of potential PK alterations is important to the ICU clinician because these changes also have the ability to adversely affect antimicrobial concentrations at infection sites, cause alterations in the PK-dependent PD properties of the drugs, and further complicate antimicrobial dosing. Knowledge of potential PK alterations and resultant changes in the probability of achieving desired PD targets pertaining to the antimicrobials used for the treatment of critically ill patients is therefore essential for selecting appropriate antibiotic dosing regimens that will optimize patient outcomes. The purpose of this chapter is to review and discuss patho-physiological changes that are known to occur in critically ill patients, the effect of these changes on antimicrobial PK properties, and current applications of antimicrobial PK/PD properties that have the potential to optimize antimicrobial use in ICU patients.

**BASIC PD PRINCIPLES**

Pharmacodynamics is the discipline that tries to define and apply the relationships between concentrations of a drug and its pharmacologic effects (both desirable and undesirable).\(^5,7,9,11\) Although both the pharmacologic activity of an agent and its PK disposition are important considerations in drug selection and dosing, it is the combination of these two properties that is critical to achieving optimal outcomes during treatment of infections. The pharmacologic activities of antibacterial drugs are commonly defined by their minimum inhibitory concentration (MIC) as determined by in vitro testing. The MIC is the minimal concentration required to inhibit the growth of a target organism; highly active agents are associated with low MICs (i.e., only low concentrations are required to inhibit bacterial growth), whereas agents with poor activity are associated with high MICs for the organism in question. It is logical that even extremely active agents with very low MICs will not be efficacious against a pathogen if the drug does not reach the infection site in sufficient quantity; likewise, agents with relatively poor activity and higher MICs may be just as clinically
efficacious if they can achieve high drug concentrations at the infection site. Pharmacodynamic considerations combine MIC-defined pharmacologic activity and PK properties of a drug to make predictions regarding the drug’s probable efficacy in the treatment of a given type of infection. Models of infection have allowed antibacterial drugs to be broadly classified into two major categories: concentration-dependent agents and time-dependent (concentration-independent) agents.\textsuperscript{5,7,11}

Concentration-dependent agents exert bactericidal activities when drug concentrations are well above the MIC of the organism; the higher the ratio of drug concentration at the infection site to the MIC, the more rapid and/or complete the bacterial killing becomes. Previous studies have established that important PD predictors of the clinical efficacy of concentration-dependent agents include the ratio of maximum serum concentration divided by the MIC (Cmax/MIC) and/or the ratio of the 24-hour area under the serum concentration versus time curve divided by the MIC (AUC\textsubscript{0-24}/MIC).\textsuperscript{5,7,11} Both Cmax/MIC and AUC\textsubscript{0-24}/MIC ratios appear to be important determinants of clinical and microbiological outcomes, although it is sometimes less clear which of these parameters is most predictive of drug efficacy because they are closely linked by the PK properties of the drugs.

Time-dependent agents exert antimicrobial effects only when their concentrations at the infection site are higher than the MIC of the pathogen; the time above MIC (T>MIC) thus becomes the PD parameter of interest for these drugs.\textsuperscript{5,7,11} More specifically, the percentage of time (relative to the dosing interval or total 24-hour period) in which the concentration of free unbound drug remains above the MIC (f T>MIC) is the key PD parameter for time-dependent antimicrobials. Studies indicate that f T>MIC should be at least 40%–50% of the dosing interval for β-lactam agents, although it has also been suggested that achieving f T>MIC for 100% of the dosing interval is desirable for optimal outcome.\textsuperscript{5,7,11} These studies have also suggested that both the AUC\textsubscript{0-24}/MIC and the f T>MIC are important predictors of clinical efficacy and the risk of developing microbial resistance.\textsuperscript{5,7,8,10,11}

Because patients in the ICU are often infected with serious
nosocomial pathogens that have decreased susceptibilities to antimicrobials and are prone to developing resistance with inadequate therapy, failure to properly dose antimicrobial agents predisposes patients to clinical and microbiological failure. The appropriate consideration of PD principles in the treatment of infection in critically ill patients enables clinicians to select dosing regimens that will maximize the potential effectiveness of the specific agent. However, the ability to adequately achieve desired PD targets for key parameters (Cmax/MIC, AUC\textsubscript{0-24}/MIC, and fT>MIC) is obviously highly dependent on the PK properties of the drugs and the ability to anticipate or compensate for potential PK alterations in individual patients.

**PK ALTERATIONS IN CRITICAL ILLNESS**

Pharmacokinetic properties that should be specifically considered in critically ill patients include distribution to various tissues and fluids, and routes of metabolism and excretion.\textsuperscript{12} The ability of a drug to penetrate to the infection site in sufficient quantities to have activity against a pathogen is crucial for achieving clinical and microbiological efficacy. Although the distributional characteristics of antimicrobials are often only specifically considered in the treatment of central nervous system or bone infections, good penetration to tissues and fluids present at the infection site is a necessary consideration when selecting agents for any infection in ICU patients. Routes of drug metabolism and elimination are also important PK properties because of the prevalence of acute and chronic organ failures in most critically ill populations. Antimicrobials are not titrated to a desired response in the same way as sedatives, analgesics, and vasopressors, and there is often a prolonged lag time between initiation of an antimicrobial regimen and occurrence of an observable or measurable response to therapy. Practitioners must therefore be familiar with the PK properties of commonly used antimicrobials as well as sources of potential PK alterations in order to use them in an efficacious and safe manner.\textsuperscript{12}

Several studies have shown that the PK of antimicrobials is often significantly altered in critical illness and that a high degree of
Interpatient (and also intrapatient) variability exists in this population. Alterations to the PK properties of antimicrobials in critically ill patients are driven by both drug- and disease-related factors. Physico-chemical properties of the molecule such as hydrophilicity and lipophilicity, molecular weight, and protein binding will influence the types of PK alterations that may be seen in the presence of pathophysiological changes in critically ill patients. Table 12.1 summarizes the relationship between hydrophilicity and lipophilicity and general PK characteristics of commonly used antimicrobials. Although the relative hydrophilicity and lipophilicity of drugs is an often imprecise predictor of PK characteristics, such information is readily available to clinicians and does offer a useful starting point for predicting the significance of potential PK alterations within individual patients.

Changes in Drug Absorption

Although oral administration of antimicrobials is not as common as intravenous administration in critically ill patients, factors that may affect the absorption of orally administered drugs are nevertheless worth discussing. The rate and extent of drug absorption after oral administration is dependent on several physiochemical properties of the drug, including molecular weight; solubility in aqueous fluids; relative lipophilicity, which will govern the ability of the drug to cross membranes of the gastrointestinal (GI) tract; net ionization state of the drug; and chemical stability of the drug at pHs found in the GI tract. Physiological factors affecting drug absorption from the GI tract include pH, blood flow to organs and tissues of the GI tract, surface area of membranes across which the drug is absorbed, and GI motility. Because many of these physiological factors are disrupted during critical illness, especially early in ICU stays when patients are not yet stable, both the rate and the extent (bioavailability) of absorption of orally administered drugs may be significantly and adversely altered. Perfusion abnormalities in patients with shock states are associated with redistribution and shunting of blood to more vital organs at the frequent expense of the GI tract. The use of vasoactive drugs often results in further reductions in regional blood flow to abdominal
This decreased perfusion of the GI tract and the attendant dysfunction adversely affect the absorption of drugs in shock states. In addition to hypoperfusion of the gut, the use of opiates in patients requiring analgesia may contribute to decreased GI motility and impaired oral absorption. Finally, patients in an unfed state (i.e., not receiving enterally administered nutrition) have been shown to rapidly develop intestinal atrophy, loss of intestinal surface area, and impaired cellular function. In light of these many causes of GI dysfunction and impaired absorption, intravenous administration is often the preferred route of drug administration in critically ill patients. This is particularly true for antimicrobials in patients with severe infections where rapid, more reliable achievement of therapeutic drug concentrations is required.

**Changes in Volume of Distribution at Steady State**

The volume of distribution at steady state (Vss) of an antimicrobial can be mathematically expressed as $C_0 = \text{dose/Vss}$, where $C_0$ is the initial concentration of a drug after administration of an intravenous bolus dose and Vss is the volume of distribution. Distribution of drugs throughout various fluids and tissues is dependent on several factors including blood flow, lipid solubility of the drug, degree of protein binding, permeability of the tissues, and pH of the fluid or tissue in relation to the net ionization state of the drug. Drugs with relatively small Vss values (less than 0.1–0.8 L/kg) are assumed to have low passive diffusion through plasma membranes and to be primarily distributed into body water, particularly intravascular and interstitial fluids. Drugs with larger Vss values (greater than 0.8 L/kg) are assumed to more freely diffuse through cell membranes and to achieve relatively greater penetration into and concentration within tissues, including adipose tissue.

During critical illness, many factors related to disease states or therapeutic interventions can alter drug distribution. Distribution of antimicrobials to infected tissues may also be affected by hemodynamic instability and regional or local changes in perfusion of various organs and tissues. Hepatic disease, renal disease or injury,
administration of large volumes of fluid such as during resuscitation regimens, and malnutrition are examples of factors that may lead to the increased Vss values of hydrophilic drugs through increased total body water and increased intravascular and interstitial fluid volumes (Table 12.2). Infections themselves are also often associated with altered Vss values. Microbial endotoxins and proteins may stimulate the production of proinflammatory mediators that may affect the vascular endothelium, resulting in vasoconstriction or vasodilatation with maldistribution of blood flow, endothelial damage, increased capillary permeability, and decreased plasma oncotic pressure.27-29 The resulting capillary leak syndrome results in fluid shifts from the intravascular compartment to the interstitial space and other anatomical spaces (i.e., third spacing)30,31; this in turn has the potential to increase the Vss of hydrophilic drugs and decrease tissue and plasma drug concentrations. The Vss of hydrophilic drugs may also be increased by the presence of other proinflammatory states such as trauma, burn injuries, mediastinitis, peritonitis, and mechanical ventilation.13-17,19,20,32-34 Such shifts in body fluid as described previously have been implicated as a major cause of alterations in Vss in critical illness. Aggressive administration of crystalloids or colloids to maintain intravascular volumes in patients with sepsis, trauma, or burns also contributes to significant third spacing and alterations in Vss. Fluid collections such as pleural effusions, ascites, peritoneal exudates, mediastinitis, and edema serve as additional reservoirs where hydrophilic drugs such as the aminoglycosides and β-lactams may be distributed, further increasing their Vss.13,14,16,32,35-47

Fluoroquinolones do not clearly fit into one specific category as being either hydrophilic or lipophilic. Fluoroquinolones are zwitterionic compounds; although often characterized as hydrophilic, they also have PK characteristics of more lipophilic compounds.

ARC = augmented renal clearance; PK = pharmacokinetic; t$_{1/2}$ = half-life; Vss = volume of distribution at steady state.

---

Decreased plasma albumin concentrations occur commonly in a wide variety of critically ill patients. Hypoalbuminemia may be the result of capillary leak syndrome, fluid overload, malnutrition, or hypercatabolic states. Reductions in plasma oncotic pressure as a result of hypoalbuminemia may result in increased fluid extravasation and third spacing, which in turn contributes to increased Vss for hydrophilic antimicrobials. Protein binding of antimicrobials that bind primarily to albumin may also be significantly altered. In the setting of hypoalbuminemia, drugs that are normally highly bound to albumin have increased proportions of unbound drug (free fraction, or f$_u$); this unbound drug is free to distribute to tissues to which the albumin-bound drug was not previously accessible. A notable example is ceftriaxone (95% bound to albumin), which has Vss values increased by as much as 90% in critically ill patients. Several drugs have been shown to have increased Vss, and sometimes increased drug clearance as well, because of altered protein binding in patients with hypoalbuminemia and increased fluid extravasation. Although antimicrobial f$_u$ is often increased in hypoalbuminemia, the actual unbound concentration of drug (C$_u$) is not necessarily increased because the reduced protein binding also causes an increased clearance of this free drug. For hydrophilic drugs, this increased clearance is often because of increased renal elimination of unbound drug through the glomerulus; any increases in C$_u$ are thus transient as the unbound drug is rapidly eliminated.

As a rule, the Vss of hydrophilic drugs is likely to be greater than
normal in critically ill patients, and peak drug concentrations are likely to be correspondingly lower after any given dose. Thus, the ability of concentration-dependent antimicrobials to meet desired PK/PD targets such as the Cmax/MIC ratio is more likely to be adversely affected by changes in Vss. Lipophilic drugs tend to be less affected by these types of changes in body water and pathophysiological changes. However, changes in Vss are highly variable and may actually be decreased in certain patients. In addition, fluid shifts alone do not completely explain changes in antimicrobial Vss because other factors (e.g., protein binding) may also be responsible for Vss alterations in critically ill patients.

Obesity represents a major challenge for accurate drug dosing in the critically ill. The clinical significance of obesity in the dosing of antimicrobials is represented by data suggesting associations between obesity and subtherapeutic antibiotic concentrations or antibiotic treatment failure.\textsuperscript{50-52} Because data are currently sparse, particularly in the critical care setting, it is difficult to make specific recommendations regarding the dosing of most antimicrobials in obesity. Obesity is known to increase the Vss of both hydrophilic and lipophilic drugs and may also be associated with increased clearance of certain drugs, particularly through enhanced clearance mechanisms.\textsuperscript{53,54} The presence of obesity should be carefully evaluated in formulating antimicrobial dosing recommendations and potential PK changes accounted for as appropriate. Although beyond the scope of this chapter, useful recommendations for dosing of antimicrobials in obesity have been published elsewhere.\textsuperscript{55-57}

**Changes in Drug Clearance**

Clearance, generally described as the intrinsic ability of the body to remove drug, is also significantly affected by the many disease processes that occur in critically ill patients. Although metabolism and excretion are two separate processes in a strictly PK sense, with respect to PK alterations in the critically ill, it is most useful to consider these processes together. Lipophilic drugs usually undergo clearance through hepatic metabolism followed by excretion of inactive
metabolites through urine, bile, or feces. Although the formation of active metabolites through hepatic metabolic pathways is common for other classes of drugs, it is unusual and largely insignificant for most antimicrobials. Hydrophilic drugs, in contrast, do not usually undergo significant metabolism and are largely eliminated through renal excretion, with the kidneys serving as the organ of clearance. Changes in drug clearance are therefore usually because of either alterations in hepatic metabolism or alterations in renal function, or both.

*Effects are dependent on net effects on renal and hepatic perfusion.

TBSA = total body surface area.
Hepatic Metabolism and Hepatic Drug Clearance

Hepatic metabolism of drugs is primarily dependent on three separate physiological processes: hepatic blood flow, intrinsic activity of metabolic enzymes, and protein binding of drugs. Models of hepatic drug metabolism include an important factor, the hepatic extraction ratio ($E_H$), which generally describes the efficiency with which a particular drug is removed (i.e., cleared) from the blood during a single pass through the liver. Although detailed descriptions of hepatic extraction ratios are beyond the scope of this chapter, it is important to recognize that drugs may be broadly classified on the basis of their hepatic metabolism as either high extraction ratio or low extraction ratio. Drugs classified as high extraction ratio ($E_H$ greater than 0.70) are metabolized by the liver with very high efficiency; their rate of metabolism and thus of drug clearance will be highly dependent on hepatic blood flow. Relatively minor changes in intrinsic enzyme activity (e.g., drug interactions involving weak to moderate inhibition of hepatic enzymes and protein binding alterations) are unlikely to cause significant changes in hepatic clearance. In contrast, the hepatic metabolism and clearance of low extraction ratio drugs ($E_H$ less than 0.30) will be highly dependent on both protein binding and the intrinsic activity of specific enzymes involved in the metabolism of those drugs. Given known or predicted changes in blood flow, intrinsic enzyme activity, and/or protein binding in a critically ill patient, characterizing a particular drug as either high or low $E_H$ is useful in predicting corresponding alterations in drug metabolism, clearance, and potential need for changes in dosing regimens.

Alterations in blood flow to the liver may commonly be seen in critically ill patients. Conditions in which significantly reduced hepatic perfusion may occur include severe sepsis and septic shock in which organ malperfusion is present, other shock states (hemorrhagic, hypovolemic, cardiogenic, anaphylactic), myocardial infarction, acute heart failure, thrombotic disorders involving the hepatic circulation, and therapeutic hypothermia. All of these various disorders are potentially associated with reduced clearance of drugs. Mechanical ventilation with or without the administration of PEEP (positive end-expiratory
pressure) has also been associated with decreased hepatic perfusion, as well as the administration of α-adrenergic agents such as epinephrine, norepinephrine, phenylephrine, vasopressin, and high-dose dopamine. Conversely, inotropic agents such as dobutamine and dopamine and vasodilators such as nitroglycerin may increase hepatic perfusion through improved hemodynamics and increasing cardiac output.

Regarding the intrinsic activity of metabolic enzymes, the induction or suppression of the metabolizing enzymes by disease state–related mechanisms or drug-drug interactions may also have significant effects on drug metabolism. Several mediators commonly present in critically ill patients have been associated with significant inhibition of both phase I oxidative metabolism involving the cytochrome P450 (CYP) system and phase II conjugative metabolism, which includes acetylation, glucuronidation, and sulfation pathways. These inhibitory mediators include stress hormones such as cortisol, epinephrine, and norepinephrine and proinflammatory cytokines including interleukin-1β, interleukin-6, and tumor necrosis factor-α. Conversely, hepatic metabolism has been shown to increase for selected medications in patients with traumatic brain injury. Both phase I and phase II metabolism has been shown to be increased in this population, raising the potential for subtherapeutic concentrations of drugs that are dependent on these metabolic pathways. Nutritional supplementation with increased amounts of dietary protein has also been shown to increase hepatic metabolism and drug clearance.

Alterations in protein binding may have important effects on the hepatic metabolism of low extraction ratio drugs. Critically ill patients commonly have alterations in plasma proteins as a result of physiological stress, including decreased concentrations of plasma albumin and increased concentrations of α₁-acid glycoprotein (AAG). Albumin concentrations are often decreased in response to hepatic processes and catabolic states, whereas AAG concentrations are known to increase in many inflammatory processes such as severe thermal injuries. Albumin binds acidic drugs, and decreased albumin concentrations potentially result in increased fₜₘ, whereas increased
concentrations of AAG result in decreased $f_u$ of basic drugs. Such changes in protein binding tend to produce temporary, offsetting changes in hepatic metabolism so that the net changes in free drug concentrations are minimal. The activity of CYP may be unchanged, increased, or decreased because of hepatocellular loss, enzyme induction, or inhibition.

The net effect of these many changes in protein binding, hepatic blood flow, effects of critical illness, or drug-drug interactions on liver function and drug clearance is extremely complex and difficult to predict in the clinical setting. Fortunately, the overall number of agents for which protein-binding alterations significantly affect drug exposure has been proposed to be relatively limited.\textsuperscript{67} In addition, for most antimicrobials, hepatic metabolism is limited, and protein binding is low enough to make little difference to their effectiveness. Specific antimicrobials for which lowering of doses in patients with severe hepatic disease would be advisable include clindamycin, metronidazole, nafcillin, erythromycin, and certain antifungals such as voriconazole, posaconazole, and the echinocandins.

**Renal Clearance of Drugs**

Renal elimination of parent drugs or their metabolites is the primary route of excretion for most pharmacologic agents, including most antimicrobial agents (Table 12.3). In critically ill patients, renal failure may occur because of several pathophysiological processes including severe sepsis and septic shock, multiple organ failure syndrome, extensive burns, trauma, hypovolemic shock, heart failure, and cardiogenic shock.\textsuperscript{13} Acute kidney injury may also be caused by drug toxicities as well as therapeutic use of vasopressors, which may cause reduced renal blood flow and decreased renal clearance of drugs.\textsuperscript{39} Because preexisting renal impairment related to underlying illnesses and acute kidney injury are common among critically ill patients of all types, decreased clearance of renally eliminated drugs is of major importance in the ICU setting. Severe renal impairment requiring renal replacement therapy is also common and presents special challenges to clinicians related to appropriate drug dosing. Although methods for
assessing renal function such as the Cockcroft-Gault (CG) and MDRD (Modified Diet in Renal Disease) equations are commonly used in the ICU because they are familiar to clinicians and simple, it must be remembered that they are also known to be relatively inaccurate in critically ill patients and do not always provide reliable measures of drug clearance.

Table 12.3  Selected Pharmacokinetic Parameters for Antimicrobials Commonly Used in Critically Ill Patients
In the absence of significant organ dysfunction, critically ill patients often have increased renal perfusion, increased glomerular filtration rates and creatinine clearance, and subsequently increased clearance of hydrophilic antibiotics.\textsuperscript{77-79} Further evidence suggests that critically ill patients have higher creatinine clearances even in the presence of normal plasma creatinine concentrations.\textsuperscript{80-85} The recognition of augmented renal clearance (ARC), defined as a creatinine clearance greater than 130 mL/minute/1.73 m\textsuperscript{2}, in many critically ill patients adds
yet another measure of uncertainty in the evaluation of renal function and drug clearance for purposes of antimicrobial dosing. Augmented renal clearance occurs at highly variable rates and has been reported to occur in 30%–86% of patients in ICUs. Specific risk factors have not been identified, although several factors have consistently been reported among various studies; these include younger age (50 years or younger), male, trauma, traumatic brain injury, mechanical ventilation, and lesser severity of illness. However, the occurrence of ARC is highly unpredictable and has also been reported among 40% of patients with sepsis, in older patients, and in patients with high severity of illness. Although the timing of onset and duration of ARC have not been well characterized, it may already be present on ICU admission and last for 1 week or more. The presence of ARC is a significant problem for antimicrobial dosing in critically ill patients because, if unrecognized, use of improperly adjusted drug doses may result in underdosing of antimicrobials, subtherapeutic drug concentrations, and therapeutic failure in the treatment of infections.

Among specific types of patients, trauma patients have commonly been reported to have increased clearance of renally eliminated drugs. However, actual studies have provided mixed results with respect to renal clearance and dosing requirements of various antibiotics in this population. Despite the apparently high incidence of ARC in this population, studies have nevertheless noted a high degree of variability in drug clearance among trauma patients. Medical and surgical ICU patients are likewise highly variable with respect to alterations in renal clearance. A review of literature reporting antibiotic PK in medical and surgical patients concluded that, although some patients did in fact have increased renal clearance, a similar number of patients had no changes or even reduced renal clearance of antibiotics. The high degree of variability in drug clearance among medical and surgical ICU patients likely mirrors the high degree of patient heterogeneity found among this population with respect to patient demographics, underlying comorbidities, and reason for admission to the ICU.

Patients with burn injuries have also been often reported to have
increased renal clearance of antibiotics. Similar to trauma patients, patients with burn injuries tend to be younger, have fewer baseline comorbidities, are initially hypermetabolic, and receive large volumes of resuscitation fluids. Many studies of this population have shown increased renal clearance compared with normal patients not in ICUs, but patients with burn injuries also tended to have a high degree of variability with respect to both increased and decreased clearance. Antimicrobials such as aminoglycosides, vancomycin, ciprofloxacin, and fluconazole usually have increased clearance, whereas individual β-lactam agents are more variable in the effects of their injuries. Clinicians should remember that patients with burn injuries often require higher daily doses of antimicrobials in order to meet desired PK/PD targets, but that such aggressive dosing may also place patients at greater risk of drug-related toxicities if patients do not actually have increased renal clearance. This is a potentially problematic finding, because drug concentrations that are much more variable than in normal subjects could result in a higher incidence of subtherapeutic or toxic concentrations. Although toxic concentrations in a patient may be detected by adverse events that manifest as clinical or laboratory abnormalities, the risk of subtherapeutic drug concentrations from rapid clearance is largely undetectable at the bedside and is compounded by the increased volume of distribution commonly seen in these patients.

**Changes in Plasma Protein Binding and Antibiotic Penetration to Tissues**

The effects of altered protein binding on Vss and hepatic drug clearance have already been described. Drugs with reduced binding to albumin or other plasma proteins may have increased $f_u$ of antibiotic, which could potentially have therapeutic implications. Because time-dependent antibiotics rely on free drug concentrations to be consistently above the pathogen MIC ($f_T>MIC$ being the key PD parameter for these agents), it is possible that increased $f_u$ of these drugs may actually contribute to enhanced therapeutic efficacy. However, decreased protein binding produces mixed effects on PK
parameters, including both Vss and clearance, which may offset the theoretical advantages. As previously discussed, decreased protein binding is often associated with increased Vss and may result in reduced concentrations of hydrophilic drugs in plasma, interstitial fluids, and other tissues through a dilutional effect. This alteration in Vss may therefore have adverse effects on concentration-dependent drugs unless doses are correspondingly increased. Protein binding alterations are not usually clinically relevant for hepatically cleared drugs because clearance of high $E_H$ drugs is not limited by protein binding and, for low $E_H$ drugs, changes in $f_u$ are often quickly offset by corresponding increases in hepatic clearance. The most relevant effect of decreased protein binding for most antimicrobials, particularly those that are renally cleared, is that increasing $f_u$ values often result in more rapid renal drug elimination. However, hypoalbuminemia and other causes for altered protein binding are only likely to significantly influence antibiotic clearance when the agent is highly protein bound (90% or greater) and has an intrinsically low Vss. Protein binding is sufficiently low for most antimicrobials that alterations in $f_u$ are not likely to pose a problem with respect to altered drug clearance (Table 12.3).

The foregoing discussion regarding the PK effects of altered protein binding largely assumes that patients have otherwise normal hepatic and renal function and will follow well-established models of PK disposition of drugs. This is obviously not the case for critically ill patients in whom significant renal and hepatic impairment is common, as well as hemodynamic changes that may alter normal processes related to Vss and clearance. Although the protein binding of antimicrobials in critically ill patients is known to be altered, the true clinical significance of these alterations is not well understood and likely varies considerably among individual patients.

Antimicrobial penetration into infection sites is also an important consideration related to the PK/PD properties of the drugs. The ability of antibiotics to penetrate to tissue sites is related to the type of antibiotic, protein binding, tissue characteristics, and method of antibiotic administration. The disposition of antibiotics has traditionally been studied by comparing tissue to serum concentration ratios in
infected and non-infected tissues. However, these studies have also shown high variability in estimates of tissue distribution. In vitro and in vivo studies suggest that high intravascular protein binding restricts the penetration of antibiotics into extravascular tissue sites. Microdialysis is an in vivo sampling technique that is being increasingly used to characterize antimicrobial tissue penetration, particularly in critically ill patients. Several studies using microdialysis techniques have shown quite good correlations between degree of protein binding and drug concentrations in interstitial fluids. However, free drug concentrations in plasma are often not representative of drug concentrations being achieved at actual infection sites because of physiological shunting or otherwise impaired tissue perfusion. Data analyses suggest that antibiotic penetration into tissues of patients with septic shock is impaired because of hemodynamic instability and regional perfusion abnormalities. Antibiotic concentrations in tissues of patients with septic shock may be 5- to 10-fold lower than in healthy volunteers or patients with less severe sepsis. Aggressive dosing of antibiotics is probably required to maximize antibiotic penetration into infected tissue, particularly in patients with shock states, although data to support this are currently lacking, and even administration of very high doses may be insufficient to overcome tissue perfusion abnormalities, which may be present in various pathophysiological processes. For highly bound antimicrobials that undergo primarily renal elimination, aggressive dosing may likewise be required to overcome potentially enhanced renal clearance in patients without renal impairment.

**Changes in Antibiotic Half-Life**

The elimination half-life of a drug is directly related to its clearance and Vss characteristics. The half-life is mathematically represented by the following equation:

\[ t_{1/2} = \frac{0.693 \times V_{ss}}{\text{clearance}} \]
The half-life of a drug is directly related to changes in both Vss and clearance; increased Vss and/or decreased clearance will increase the half-life, whereas decreased Vss and/or increased clearance will decrease the half-life. An increase in Vss that prolongs the half-life might be therapeutically advantageous for time-dependent antimicrobials from a PK/PD perspective but a potential disadvantage for concentration-dependent agents that are dependent on achieving adequate Cmax concentrations. The same considerations could apply to reductions in drug clearance, which would also potentially be advantageous for time-dependent antimicrobials because of the reduced elimination rates and maintenance of drug concentrations over longer periods. However, such generalizations do not adequately represent the complexities of the many patho-physiological processes that influence Vss and clearance (often simultaneously), the dynamic nature of critically ill patients in whom PK properties of drugs may be changing on a daily (if not hourly) basis because of therapeutic interventions and evolving pathophysiological processes, or the significant difficulties in adequately assessing and characterizing the potential PK alterations that may be present in an individual patient. Although it is predictable that PK alterations are occurring in many critically ill patients, it is also extremely difficult for clinicians to make informed dosing decisions on the basis of accurate estimates of the magnitude of these changes.

General Strategies for Dosing Adjustments Based on PK Alterations

A general strategy for assessing the need for potential dose adjustments of antimicrobials in critically ill patients is first to determine whether the specific drug is primarily cleared through hepatic metabolism or renal excretion. As previously discussed, antimicrobials that are heptically metabolized do not generally require dosage adjustments in ICU patients unless significant hepatic dysfunction is present. For drugs that are renally cleared, reduction in total daily doses may be considered in the presence of renal impairment, whereas the presence of certain other conditions (Table 12.2) should
prompt clinicians to consider increasing total daily doses. Clinicians should also consider increasing doses of hydrophilic drugs in the presence of conditions that are associated with increased Vss values of these agents (Table 12.2). Beyond these simple considerations, determining if and how antimicrobial regimens should be appropriately adjusted in ICU patients becomes much more difficult.

Because of the severity of infections encountered in critically ill patients and because of the variability in PK, tissue penetration, presence of obesity, pathogen MICs, and other factors relating to the efficacy of antimicrobials, the general recommendation for antimicrobials in ICU patients is to use high, aggressive initial doses. Aggressive dosing of antimicrobials (at least during empiric therapy in high-risk patients) should be a standard practice in ICUs to optimize the PD performance of the drugs. Use of high initial doses (until pathogens and susceptibilities are determined and/or patients show favorable clinical response) potentially compensates for PK variability that may be present and helps ensure that patients are receiving enough drug to successfully achieve the PD goals of antimicrobial use. Reliable attainment of key PK/PD targets (AUC$_{0-24}$/MIC, Cmax/MIC, and T>MIC) depends on being able to adequately estimate the PK disposition of antimicrobials in individual patients. Beyond PK considerations, the other important variable in PD targets is the pathogen MIC. As bacterial pathogens encountered in the ICU continue to become less susceptible with higher MICs,$^{107-112}$ the use of aggressive initial dosing regimens becomes even more important because the selected dosing regimens have to allow for the elevated MICs as well as variability in PK parameters.$^{107}$ Given the extreme variability of PK parameters such as Vss and clearance and the inability to precisely assess renal function, hepatic function, protein binding, and tissue penetration of antimicrobials in critically ill patients, clinicians should err on the side of aggressive dosing in order to avoid being too conservative with administered regimens.$^{16,20,76,113}$ However, use of high doses also places patients at higher risk of drug-related adverse effects and toxicities, again partly owing to PK variability in drug Vss and clearance. Although drug dosing should be aggressive, it
must also be based on appropriate clinical considerations involving relevant issues such as appropriate PK/PD goals, careful clinical assessment for the presence of renal or hepatic dysfunction that may lead to drug accumulation, presence of obesity, the presumed infection site and the ability of the drug to achieve adequate concentrations in that site, susceptibilities of presumed or documented pathogens to the drugs in question, and potential drug toxicities.

Because achieving appropriate PK/PD targets for antimicrobials is an important predictor of clinical efficacy and the risk of developing microbial resistance, clinicians must take care not to underdose antimicrobials in critically ill patients. Given the known inaccuracies in estimating creatinine clearance on the basis of serum creatinine, clinicians should not rely on estimated creatinine clearance as a sole consideration for choosing drug dosing regimens in patients with renal impairment. Apparently, “proper” dosing adjustments on the basis of estimated creatinine and published recommendations for dose adjustment (e.g., product package inserts) may effectively reduce total drug use and drug cost and potentially also reduce adverse effects of some drugs. However, given the need to achieve PD targets in the setting of variable PK parameters and difficult pathogens, even high doses of many drugs are already marginal, and alternative dosing strategies are sometimes necessary.113-117 Because serum creatinine–based methods of assessing renal function are notoriously inaccurate for predicting drug clearance in ICU patients,70-76 clinicians should not try to “fine-tune” dose adjustments because doing so may place some patients at risk of treatment failure. For example, in a severely infected patient with a creatinine clearance estimated at 48 mL/minute by the CG method, antimicrobial doses should not necessarily be reduced just because the product labeling specifies dose reduction at calculated creatinine clearances less than 50 mL/minute. Rather, clinicians must consider potential risks to the patient (drug toxicities, etc.) versus the potential benefits to be gained by administering higher doses than those recommended, at least until the patient starts having a response to antimicrobial therapy.20,116

Given the apparently high prevalence of ARC and the potential for
patients to be underdosed in this setting, clinicians should be alert to patients who fit the currently recognized risk factors for ARC (young, male, trauma, low severity of illness, etc.) and be prepared to administer higher-than-normal doses to such patients. Recognition of ARC also depends on accurate assessment of renal function. Because serum creatinine–based methods are not reliably accurate, including among patients with ARC, the use of timed urinary creatinine measurements should be standard practice when more accurate assessment of renal function is needed. Although timed urinary creatinine measurements are also not completely accurate, this method is generally recognized as providing somewhat more accurate estimates of GFR (glomerular filtration rate) in critically ill patients. Because U.S. Food and Drug Administration (FDA)-labeled dosing of antimicrobials does not specifically address recommended doses in patients with a creatinine clearance greater than 130–150 mL/minute and no other formal dosing recommendations exist for patients with ARC, clinicians will need to exercise their best judgment in determining appropriate doses. One recent study found that 55% of patients in a medical/surgical ICU receiving standard doses of meropenem (1 g every 8 hours) or piperacillin/tazobactam (4.5 g every 6 hours) did not meet the PK/PD targets intended to treat Pseudomonas aeruginosa infections, even when 3-hour extended infusions were used for drug administration.

Therapeutic drug monitoring (TDM) of aminoglycosides and vancomycin is common in current practice and is considered a standard of care for patients receiving these agents. Because of the extreme PK variability of β-lactam agents in ICU patients, routine TDM has been suggested for these drugs as well. The ability to routinely measure and adjust β-lactam concentrations could be very advantageous in detecting patients with significant alterations in PK parameters and adjusting doses to more effectively meet PD targets. Unfortunately, β-lactam assays are not routinely available to most hospital laboratories or clinicians, and TDM for β-lactam antibiotics is not currently feasible. Plasma concentrations of certain antifungal agents such as voriconazole and posaconazole are also occasionally
measured, and a routine role for TDM has been advocated,\textsuperscript{124-127} but routine TDM practices for antifungal agents have not yet been established. For most antimicrobials, reliance on population PK studies and close clinical monitoring for evidence of clinical response to therapy and drug toxicities remain the only available option.

In light of the many challenges in determining appropriate dosing of antimicrobials, newer dosing strategies (e.g., extended infusions for β-lactams) may play an important role in optimizing drug therapy in order to more reliably meet desired PK/PD goals. Such strategies have been purposely developed and studied in order to provide more reliable and effective dosing options for treatment of difficult pathogens in severely ill patients. Critically ill patients certainly have many risk factors for poor outcomes of antimicrobial therapy, and newer dosing options as discussed in later sections of this chapter should be considered for patients in the ICU.

\section*{PD CONSIDERATIONS FOR DRUG DOSING IN THE ICU}

The rate and extent of the activity of an antimicrobial drug is dependent on many factors including the interaction between drug concentrations at the infection site and the MIC of the pathogen. A change in the PK properties of an antimicrobial agent may therefore affect the activity of the drug against a particular pathogen and may also affect the outcome of therapy. Conversely, developing dosing regimens that optimize the PK characteristics of the drug in relation to the MIC potentially improve clinical responses, accelerate the rate of clinical response with the potential for reducing durations of drug therapy, and minimize the risk of developing antibacterial resistance. An understanding of the PD properties of drugs, which describe the nature of such PK-MIC interactions, is necessary in order to make informed decisions regarding selection of an appropriate regimen for a given patient. Given the potential for extreme variability of antimicrobial PK properties in critically ill patients, maximizing the PD “performance” of a drug is often very challenging. However, a working knowledge of the PD relationships of various drugs as well as an understanding of critical
illness maximizes the potential for optimizing dosing regimens for individual critically ill patients. Clinicians also need to be familiar with MICs relevant to the chosen antibacterial agent for suspected or known pathogens in the ICU setting. The remainder of this chapter will review currently recommended PK/PD targets for common antimicrobials, discuss examples of clinical applications of PD principles, and describe potential limitations to the application of PK/PD in the clinical setting.

**PD Goals**

Pharmacodynamic parameters correlating with antimicrobial efficacy have been widely published and are summarized in Table 12.4. These parameters have been determined from in vitro and in vivo studies and, for many drugs, also validated in humans through clinical data obtained either retrospectively or prospectively. It is important to recognize that these targets have sometimes been modified over time as additional studies are performed and our understanding of PK/PD relationships is increased. However, PD parameters summarized in Table 12.4 reflect our current understanding of the complex relationships governing antimicrobial actions and efficacy. Because plasma or tissue concentrations are not routinely measured for most of these agents, computer modeling techniques such as Monte Carlo simulation (MCS) form the basis for dosing recommendations that seek to maximize the attainment of PD goals in patients requiring antimicrobial therapy.

**Antibacterials**

**Time-Dependent Drugs**

In general, the goal of a dosage regimen for a time-dependent antibiotic is to optimize the duration of drug exposure above the MIC. Although meeting a minimum effective concentration of drug is also necessary, increasing the concentration beyond 4–6 times the MIC does not appear to result in enhanced killing but may instead require
unnecessarily high doses of drug.\textsuperscript{5,7,11} Once effective concentrations have been reached, extending the time those concentrations remain above the MIC should enhance antibacterial activity and presumably efficacy as well. The \( f\ T>MIC \) is the PK/PD parameter considered most predictive of bactericidal activity of many time-dependent antimicrobials such as the \( \beta \)-lactams, although the \( AUC_{0-24}/MIC \) is a good predictor of efficacy for some time-dependent drugs such as vancomycin and linezolid.\textsuperscript{5,7,8,11,131}

b For Streptococcus pneumoniae.
c Specific goal value not determined.
d For treatment of Candida infections.
e For treatment of Aspergillus infections.

AUC<sub>0-24</sub>/MIC = ratio of the 24-hour area under the serum concentration versus time curve divided by the MIC; Cmax/MIC = ratio of maximum serum concentration divided by
the MIC; fAUC\textsubscript{0-24}/MIC = ratio of the 24-hour area under the serum concentration versus time curve for unbound/free drug divided by the MIC; fCmax/MIC = ratio of maximum serum concentration of unbound/free drug divided by the MIC; fT>MIC = time during which unbound/free drug remains above the pathogen MIC; MIC = minimum inhibitory concentration; PD = pharmacodynamic; PK = pharmacokinetic; TDM = therapeutic drug monitoring.

For β-lactam antibiotics, in vitro and in vivo studies have shown that f T>MIC is the best predictor of bacterial killing and microbiological response against gram-negative bacteria.\textsuperscript{5,7,8,11} However, these studies have also shown that the specific f T>MIC target is different for the various types of β-lactam antibiotics.\textsuperscript{5,7,8,11} For penicillins, an f T>MIC of 30% produces bacteriostatic effects on bacteria, whereas a 50% f T>MIC is required for maximal bactericidal effects. Cephalosporins require somewhat greater f T>MIC than do penicillins: 35%–40% for bacteriostatic activity and 60%–70% for bactericidal effects. For bacteriostatic and bactericidal effects, the carbapenems require f T>MIC values of about 20%–30% and 40%, respectively.

The AUC\textsubscript{0-24}/MIC ratio is the best PK/PD predictor of response to vancomycin therapy according to data from animal models and in vitro studies. Those studies suggest that an AUC\textsubscript{0-24}/MIC ratio of at least 350–400 is essential for a good clinical outcome.\textsuperscript{132,136-141} The current recommendations to target trough vancomycin concentrations of 15–20 mg/L for treatment of severe infections are based on the fact that these trough concentrations correlate with AUC\textsubscript{0-24}/MIC values of 350–400 or greater in the treatment of Staphylococcus aureus infections caused by strains with MICs less than 1 mg/L.\textsuperscript{136-140}

Linezolid is also a time-dependent antibiotic that has been associated with both f T>MIC and AUC\textsubscript{0-24}/MIC as the parameters that best describe its antibacterial activity.\textsuperscript{131,142} Clinical efficacy of linezolid has been correlated with an f T>MIC of 85% and greater and an AUC\textsubscript{0-24}/MIC greater than 85.\textsuperscript{131} Similar numbers have also been associated with high microbiological cure rates, which may in turn relate to reduced risk of selecting gram-positive resistance to linezolid.\textsuperscript{131}
Concentration-Dependent Drugs

The PD parameters associated with bactericidal effects of concentration-dependent drugs include both Cmax/MIC and AUC$_{0-24}$/MIC ratios. Aminoglycosides and fluoroquinolones are among the antibiotics that have these PK-PD relationships. In vitro time-kill studies have shown that the rate and extent of bactericidal activity increases as antibiotic concentrations increase in relation to the bacterial MIC for these drugs.$^5$ Bactericidal activity and clinical efficacy of the aminoglycosides have been associated with a Cmax/MIC ratio of greater than 8–10.$^{143-146}$ The AUC$_{0-24}$/MIC has also been studied as a determinant of clinical efficacy, and it has been suggested that this parameter is a better indicator of total aminoglycoside exposure.$^{144,146-148}$ Several studies have evaluated the AUC$_{0-24}$/MIC and determined that a target of 80–125 is a good predictor of bactericidal killing and antibacterial efficacy in animal models. Although the exact AUC$_{0-24}$/MIC target is unknown and may in fact vary somewhat depending on bacterial organism and type of infection being treated, the range of 80–125 seems to provide the best combination of maximizing the probability of clinical efficacy while minimizing nephrotoxicity risk.$^{144,146-148}$

Studies have clearly shown that the fluoroquinolones have concentration-dependent bacterial killing.$^{148-153}$ Many studies, including a prospectively developed model of the PD response to levofloxacin during treatment of respiratory tract, skin, and urinary tract infections, have provided evidence that achieving a Cmax/MIC ratio of greater than 10–12 appears to be predictive of clinical drug efficacy and successful bacterial eradication.$^{148-153}$ The AUC$_{0-24}$/MIC has also been shown in vitro and retrospectively in vivo to be predictive of favorable clinical response and reduced development of resistance.$^{148-153}$ Although the optimal AUC$_{0-24}$/MIC ratio breakpoints are still unclear, favorable AUC$_{0-24}$/MIC ratios appear to be 125–250 for gram-negative organisms and 30–50 for S. pneumoniae.$^{148-153}$ These PD targets are generally applied to all currently used fluoroquinolones including ciprofloxacin, levofloxacin, and moxifloxacin. Whether either the
Cmax/MIC ratio or the AUC_{0-24}/MIC ratio is superior to the other parameter and which specific ratios are most predictive of drug efficacy remain somewhat controversial; however, the strong relationships between these PD parameters and the clinical and microbiological outcomes during fluoroquinolone therapy have been well established.

Daptomycin is important to note among other the other concentration-dependent drugs. Although PK/PD parameters best associated with clinical and microbiological efficacy of daptomycin have not been well established, its concentration-dependent properties serve as the basis for use of doses larger than the 4- to 6-mg/kg (depending on indication) doses currently recommended in the manufacturer’s approved labeling. Clinical data definitively showing improved outcomes of these higher doses (e.g., 8–12 mg/kg) are not yet available, although daptomycin has been shown to be safe and well tolerated at these doses.

**Antifungals**

Similar to antibacterial agents, antifungal drugs have different PK/PD properties in vivo. These patterns of activity may be correlated with drug dose and pathogen MIC to identify dosing strategies that maximize antifungal efficacy while reducing the risk of toxicity. Similar to antibacterial drugs, inadequate dosing of antifungals may contribute to both treatment failure and the emergence of resistance. With the increasing prevalence of non-albicans Candida spp. and their reduced susceptibility to certain antifungal agents, appropriate choice and dosing of antifungals is essential for optimizing clinical outcomes and minimizing resistance. Pharmacodynamic data may also be useful for predicting infection sites where antifungal drugs have a higher risk of treatment failure because of poor tissue penetration and resultant low drug concentrations.

Although for many years there was a paucity of data related to antifungal PK/PD properties, these characteristics have more recently been reasonably well characterized and are increasingly recognized as
potentially important factors for drug selection in the treatment of invasive fungal infections. Although PD principles are best established for Candida bloodstream infections, PK/PD principles have more recently also been successfully applied to the treatment of molds including Aspergillus spp. Of interest, PD characteristics of antifungal agents can be described using the same PK/PD parameters as those used for antibacterial drugs: Cmax/MIC ratio, AUC$_{0-24}$/MIC ratio, and T>MIC. For the antifungal agents, these parameters all seem to be best correlated with free unbound concentrations of drug; thus, the following terms will be used to describe the PK/PD properties of the antifungals as they relate to free drug concentrations: fCmax/MIC ratio, fAUC$_{0-24}$/MIC ratio, and f T>MIC. These descriptions of antifungal PK/PD goals will of necessity be very brief, but several excellent review articles are available that provide comprehensive overviews of how antifungal PK/PD goals were derived and how they should be applied clinically.

**Time-Dependent Drugs**

Flucytosine appears to be the only antifungal agent that has time-dependent antimicrobial activity in a manner similar to time-dependent antibacterials such as the β-lactams. Flucytosine has fungistatic activity against Candida spp. with 40% f T>MIC being the apparently optimal measure of drug exposure. This f T>MIC of 40% has been associated with favorable clinical outcomes in several studies.

**Concentration-Dependent Drugs**

Fluconazole and the other azole-type antifungals have concentration-dependent PD properties and are best characterized against Candida spp. by fAUC$_{0-24}$/MIC. AnfAUC$_{0-24}$/MIC of 25 or greater (using the Clinical and Laboratory Standards Institute [CLSI] MIC method) has been reported to maximize the efficacy of fluconazole with improved clinical outcomes shown in in vitro, in vivo, and clinical studies. This same PD target of fAUC$_{0-24}$/MIC of 25 or greater
appears to also describe other azoles reasonably well; clinical trial data analyses from mucosal and systemic candidiasis have identified a similar PD target for voriconazole and itraconazole. Clinical data analyses regarding PD targets in the treatment of Aspergillus spp or other invasive molds remain limited. However, in patients receiving voriconazole for invasive aspergillosis for whom drug monitoring and clinical outcome data were available, rates of clinical success and survival were significantly higher in patients who achieved serum trough concentrations of 1–2 mg/mL. Factoring in protein binding characteristics and the MIC for Aspergillus isolates, the resulting value for $f_{AUC_{0-24}}/MIC$ was again around 25.

In contrast to the azoles, amphotericin B deoxycholate has concentration-dependent fungicidal activity against Candida spp., and its efficacy is best correlated with an $f_{Cmax}/MIC$ ratio of 2–4. Unfortunately, few data exist for the lipid formulations of amphotericin B (LAMB). According to a study of children that included a small cohort with invasive aspergillosis, maximal antifungal efficacy of LAMB was observed with an $f_{Cmax}/MIC$ greater than 40.

Echinocandins also have concentration-dependent fungicidal activity against Candida spp., and both $f_{Cmax}/MIC$ and $f_{AUC_{0-24}}/MIC$ have been associated with clinical efficacy. Studies of both animal models and patients with invasive candidiasis have identified similar PD targets with maximal antifungal efficacy achieved at an $f_{AUC_{0-24}}/MIC$ near 10. Data analyses defining PK/PD targets for treatment of invasive aspergillosis with echinocandins are few. However, one study found an $f_{Cmax}/MIC$ ratio of 10–20 to be associated with maximal efficacy.

**Antivirals and Antiprotozoals**

Although antiviral agents such as acyclovir and ganciclovir are used with regularity in the ICU, the PD properties of antiviral agents are not well characterized, and no formal PK/PD-based dosing recommendations can be made. Aggressive dosing in seriously ill patients, thoughtful assessment of organ function with recommended
dosage adjustments made as appropriate, and close monitoring of patients for evidence of clinical response and drug-related toxicities continue to be the mainstays of antiviral use in the ICU. Similarly, the PDs of antiprotozoal drugs have not been well described, and no formal recommendations for use in ICU patients can be made.

---

**CLINICAL APPLICATIONS OF PD PRINCIPLES IN THE CRITICALLY ILL**

**Prolonged and Continuous Infusions of β-Lacam Antibiotics**

Optimization of drug exposure for time-dependent antibiotics such as the β-lactams requires maintaining antibiotic concentrations above the MIC for prolonged periods. With an increased understanding of PK/PD characteristics of the β-lactams, there has also come a concern that the traditional method of administering antibiotics by intermittent short-infusion methods may not actually optimize drug use in many patients. As has been previously reviewed, significant alterations in β-lactam PK parameters may lead to significantly reduced total drug exposure in critically ill patients. Increases in Vss may reduce peak concentrations after intermittent dosing, whereas increases in clearance (as with ARC) may further significantly reduce the period during which antibiotic concentrations remain above the pathogen MIC. Intermittent dosing of β-lactams may therefore result in a concentration versus time profile that actually minimizes the chance of achieving an optimal PD profile and favorable clinical outcome, particularly in patients with potentially significant PK alterations. Intermittent dosing of β-lactams has historically produced excellent clinical efficacy in the treatment of infections caused by susceptible pathogens with very low MICs. However, as multidrug-resistant pathogens such as P. aeruginosa have become more common and even susceptible strains often have relatively high MICs (often at or near the susceptibility breakpoint), potentially suboptimal intermittent dosing of β-lactams has become of more concern.
There are several potential methods of increasing the time-dependent PD exposure of β-lactams antibiotics, including increasing the daily dose using higher doses or dosing more often, administering the drug by continuous infusion, and administering the drug by prolonged infusion (or extended infusions) (i.e., increasing administration time from 0.5–1.0 hour to 3–4 hours). Administering higher daily doses by increasing dose or frequency is usually less desirable because it is more expensive, may place patients at higher risk of drug-related adverse effects and toxicities, and increases workload of hospital personnel. Moreover, from a PK/PD standpoint, using higher daily doses is inefficient because doubling the dose of β-lactams leads to an increased f T>MIC of only one additional half-life (only about 1 hour for most agents). 174

There has been a renewed interest in administering β-lactam antibiotics by a 24-hour continuous infusion because this represents an efficient way of optimizing the PD to achieving a 100% f T>MIC for even high-MIC pathogens while minimizing the risk of drug toxicities and using the least amount of total daily drug, drug supplies, and labor costs. Continuous infusion is also attractive for many β-lactam antibiotics because of their relatively short half-lives. 174 Continuous infusions of β-lactams consistently provide better PD parameters than does intermittent dosing in less susceptible bacteria, although the method of dosing is not as critical in highly sensitive strains. 106,175-180 Continuous infusions may also achieve higher tissue concentrations than intermittent dosing. 105

Although administration of continuous infusions has many potential advantages, this administration strategy may not be practical in all patients. The use of continuous infusion medications generally requires a dedicated intravenous line to prevent potential incompatibilities and allow for concomitant administration of other intravenous medications. However, it is often not practical to dedicate a catheter line for an entire 24-hour period in critically ill patients who often require many other medications as well as fluids, blood products, and other reasons for intravenous access. 128 In addition, given that antibiotics administered by continuous infusion are ideally best prepared once
daily and infused at room temperature over the full 24 hours, antibiotic stability may be insufficient under those conditions.\textsuperscript{128} The carbapenems in particular are relatively unstable at room temperature and may require preparation of fresh doses several times daily in order to be infused throughout the 24-hour day.\textsuperscript{181-183} Patients most likely to benefit from administration as continuous infusions are those infected with less susceptible bacteria with high MICs at or near their susceptibility breakpoints. As MICs potentially continue to increase, continuous infusion may become more beneficial because of the enhanced PD target attainment at higher MICs.\textsuperscript{128,129,174,178} However, for antibiotics with short room-temperature stability (e.g., carbapenems) or for use in critically ill patients for whom dedicated line access is not feasible, continuous infusions may not be the most viable option for antibiotic administration.\textsuperscript{128}

Clinicians must also recognize that achieving the potential benefits of a continuous infusion assumes that the proper dose is being administered and that the pathogen MIC is in fact being exceeded by concentrations achieved at a given infusion rate. Use of inadequate total daily doses, particularly in the management of infections caused by pathogens with high MICs at or near the susceptibility breakpoint, has the potential for producing subtherapeutic concentrations that inconsistently (or even never) exceed the MIC and therefore could increase the risk of treatment failure.

Extending β-lactam administration times over periods that are longer than intermittent infusions (0.5–1.0 hour) but shorter than 24-hour continuous infusions is another strategy that is becoming increasingly popular in clinical practice. Administering β-lactams as a typically 3- to 4-hour prolonged infusion allows drug concentrations to remain in excess of the MIC for a longer period than would be possible after intermittent short infusions. This potential advantage also holds true against organisms with high MIC values where differences between prolonged infusion and intermittent infusion became more pronounced.\textsuperscript{184-186} With respect to achieving desired f T>MIC PD targets, continuous and prolonged infusion strategies often produce very similar profiles; modeling studies have generally shown little
difference between continuous infusions and prolonged infusions in achieving desired f T>MIC PD targets. Finally, use of prolonged rather than continuous infusions may help resolve issues related to drug stability and intravenous line access. Maximizing carbapenem exposure through use of prolonged infusions may allow for more aggressive dosing in patients with severe infections and/or those infected with pathogens with high MICs while still providing cost-effective therapy. Because there appear to be few clinically relevant differences in achieving f T>MIC targets or proven clinical efficacy with prolonged infusions of carbapenems compared with continuous infusions, and because prolonged infusions avoid potential drug stability issues, it is recommended that carbapenems be administered over 3- or 4-hour infusion times. Likewise, prolonged and continuous infusion regimens of piperacillin/tazobactam provide similar probabilities of meeting f T>MIC targets when the same total daily doses are administered. Similar to carbapenems, administration of piperacillin/tazobactam by prolonged 4-hour infusions is recommended over continuous infusions.

Of note, antibiotic therapy with continuous infusions should always be initiated with a loading dose. The ability to significantly improve the achievement of f T>MIC targets also depends on rapidly attaining steady state–like concentrations of antibiotics that are at or near desired target concentrations. Although the β-lactam antibiotics that are most likely to be administered by continuous infusion have short half-lives (about 1 hour) in patients with normal renal function, it will still require 5 hours or more to reach steady state at desired concentrations; it will take even longer in patients with reduced drug clearance and longer half-life. For this reason, as a rule, antibiotic loading doses should always be administered at the initiation of continuous infusion regimens.

The β-lactam antibiotics that have been most extensively studied using alternative continuous and prolonged dosing regimens include piperacillin/tazobactam, cephalosporins (ceftazidime, cefepime), and the carbapenems (imipenem, meropenem, doripenem). Perhaps the most significant of the early studies of the potential benefits of
prolonged-infusion regimens was a retrospective pre-post trial evaluating implementation of prolonged-infusion piperacillin/tazobactam regimens in an academic medical center. Clinical outcomes achieved with piperacillin/tazobactam 3.375 g administered as standard infusions every 4 or 6 hours were compared with those obtained after switching to 3.375 g every 8 hours administered as a 4-hour prolonged infusion. All patients included in the study were being treated for P. aeruginosa infections. Overall, no significant differences in either 14-day all-cause mortality or hospital length of stay were observed across the entire population of 194 patients. However, when patients were stratified according to severity of illness as determined by Acute Physiology and Chronic Health Evaluation II (APACHE II) scores, significant differences in both mortality (12.2% in the prolonged infusion group vs. 31.6% in the short infusion group; p<0.04) and hospital length of stay (median 21 vs. 38 days, respectively; p<0.02) were observed among the cohort of more severely ill patients with APACHE II scores of 17 or higher. The significance of this study was that it highlighted the importance of optimizing antibiotic dosing in the subset of patients who are most likely to see clinical benefit: high severity of illness, potential for significant PK alterations, and infection with difficult pathogens most likely to have higher MICs.

The PD, clinical efficacy, and safety data for piperacillin/tazobactam, cephalosporins, and carbapenems when administered as continuous or prolonged infusion regimens have been extensively reviewed and at least four different meta-analyses conducted to determine whether these alternative dosing strategies can be recommended over traditional intermittent dosing (Table 12.5). Two earlier meta-analyses addressing continuous infusion regimens compared with intermittent dosing regimens found that continuous antibiotic infusions were associated with statistically significant improvements in neither clinical cure rates nor mortality. Although it was observed that patients with a higher acuity of illness had a greater response to the continuous infusion regimens, echoing the results of the earlier study of piperacillin/tazobactam prolonged infusions, no definitive recommendations could be made because of several limitations of the
data at that time: limited numbers of randomized controlled trials, usually small patient numbers, inadequately powered, and designed as pilot studies or noninferiority studies. However, two more recent meta-analyses concluded that continuous or prolonged β-lactam infusions were associated with statistically significant reductions in mortality. Although these studies are more recent and had conclusions more favorable for alternative dosing strategies, both studies were beset by the same limitations as the two earlier meta-analyses and emphasized the need for well-designed, larger, multicenter, randomized controlled trials in order to clearly define the role of continuous or prolonged infusion regimens. Indeed, the need for additional well-conducted studies is highlighted by a recent study that compared intermittent dosing with continuous infusions of various β-lactams including piperacillin/tazobactam, ticarcillin/clavulanate, and meropenem. This was a prospective, double-blind, randomized, controlled, multicenter trial, apparently the first such trial ever to have been conducted for evaluation of this particular question. The study end points were trough unbound plasma antibiotic concentrations above the MIC of the isolated pathogens on days 3 and 4, clinical response 7–14 days after the last dose of study drug, ICU-free days at day 28, and hospital survival. Sixty patients were enrolled: 30 each in the intermittent and continuous infusion groups. Results of the study showed statistically significant differences in trough unbound plasma concentrations exceeding the MIC (82% continuous vs. 29% intermittent; p=0.001) and clinical response (70% continuous vs. 43% intermittent; p=0.037). However, no differences between groups were found with respect to ICU-free days (p=0.14) or hospital survival (p=0.47). Additional large, well-designed studies of this type are required to truly define the role of β-lactam administration by continuous or prolonged infusion and the clinical benefits to be expected.

</table>
Several studies have examined the potential pharmacoeconomic benefits of continuous or prolonged β-lactam infusions, but the results of these studies are somewhat inconsistent and are highly dependent on study methodologies and the actual total daily dose of drug administered.\textsuperscript{176,193-198} Although most studies have determined that alternative dosing strategies result in substantial cost savings relative to intermittent administration, particularly related to labor and supply costs, other studies have not shown such savings.\textsuperscript{196} Although the potential for significant cost savings is somewhat institution-dependent and will vary with specific drugs and doses used, there is no question that β-lactam administration by constant and prolonged infusion regimens are associated with other potential advantages. Chief among these are the more reliable achievement of \( f \ T>MIC \) targets and potential for improved clinical outcomes in high-risk patients who will likely derive the greatest benefit from optimization of PK/PD parameters.
Continuous Infusions of Vancomycin

It has been proposed that vancomycin, another time-dependent antibiotic, also benefits from administration by continuous infusion for reasons similar to those discussed for the β-lactam drugs. Increasing vancomycin MICs for methicillin-resistant S. aureus have been noted in recent years and are a great concern for the continued successful clinical use of vancomycin. Higher MICs will reduce the AUC$_{0-24}$/MIC ratio achieved with any given dose, and desired AUC$_{0-24}$/MIC targets are unlikely to be achieved with standard vancomycin doses (i.e., 1 g every 12 hours) once the MIC increases to 1 mg/L and beyond. In addition, vancomycin has been noted to have highly variable PK disposition in critically ill patients and to achieve subtherapeutic concentrations in a high proportion of patients after standard intermittent dosing. Finally, the use of higher vancomycin doses in an effort to overcome the effects of increased MICs and still achieve desired AUC$_{0-24}$/MIC targets has been associated with higher rates of nephrotoxicity. Continuous infusions of vancomycin have thus been advocated as a means of optimizing the PD of the drug while minimizing nephrotoxicity. Several studies report that continuous vancomycin infusions provide improved penetration and increased drug concentrations in cerebrospinal fluid and respiratory tissues. Several studies, both retrospective and prospective, have also evaluated PK and clinical outcomes in patients receiving continuous infusions of vancomycin compared with standard intermittent dosing. Studies have consistently shown that continuous infusion regimens more consistently achieve desired plasma concentrations of 20–25 mg/L (i.e., trough concentration with intermittent dosing, average concentration with continuous infusion) and in many cases are also able to achieve target concentrations significantly more rapidly after initiating therapy. One study found that although there was no significant difference in AUC$_{0-24}$/MIC ratios between the two groups, patients receiving continuous infusions were markedly more likely to achieve and maintain desired plasma concentrations. Other studies have also suggested that continuous vancomycin infusions either reduce the
overall incidence of nephrotoxicity or substantially delay the onset. However, what is significantly lacking in these studies are definitive data analyses showing improved response to vancomycin therapy and reductions in patient mortality. Individual studies have generally shown comparable efficacy between standard and continuous regimens. A meta-analysis evaluating continuous versus intermittent infusions of vancomycin for the treatment of gram-positive infections found no statistically significant difference in mortality rates in patients receiving the two regimens, although this analysis did find a significant reduction in nephrotoxicity in patients receiving continuous infusions (relative risk 0.63; 95% confidence interval, 0.43–0.94). In summary, available data analyses suggest that continuous vancomycin infusions are a promising method of drug administration in patients with serious gram-positive infections. The ability to reach target drug concentrations more rapidly while having less PK/PD variability is potentially beneficial in the treatment of severe infections in high-risk patients, as is the possible reduction in nephrotoxicity. However, until more definitive data can provide evidence of clear benefits related to improved clinical outcomes, current guidelines recommend against the routine use of continuous infusions of vancomycin.

As with β-lactam drugs, if continuous vancomycin infusions are to be used, it is important that therapy be initiated with a loading dose of vancomycin before initiating the drug infusion.

**Continuous Infusions of Linezolid**

According to the previous discussions of continuous infusions of β-lactams and vancomycin, it is perhaps not surprising that continuous infusions of linezolid have also been explored. Linezolid, also a time-dependent drug, potentially has the same PK/PD limitations as the β-lactams and vancomycin, and it could perhaps benefit from continuous administration with respect to overcoming PK variability, improving tissue penetration of the drug, and maximizing achievement of PD targets. One study compared the PK/PD profile of standard intermittent infusions with continuous infusions of linezolid in critically ill patients with sepsis. Continuous infusion was superior to intermittent
infusions in achieving and maintaining PD targets. Of interest, a study of an animal model not only showed that continuous infusions of linezolid are more effective than intermittent infusions, but also that the drug behaved as a bactericidal rather than a bacteriostatic agent. Clinical studies are needed to define whether continuous linezolid infusions are associated with improved patient outcomes and cannot be recommended at this time.

**Extended-Interval Dosing of Aminoglycosides**

Extended-interval dosing (or once-daily dosing) of aminoglycosides is perhaps the best-known example of direct application of PK/PD principles in the clinical care of patients. Being a concentration-dependent drug, aminoglycosides have been shown to eradicate organisms most effectively when peak plasma concentrations that are 10 times or greater above their MIC (i.e., Cmax/MIC of 10 or greater) are achieved. The concept behind extended-interval dosing is that by administering large doses at infrequent intervals (rather than smaller doses at frequent intervals), achievement of favorable Cmax/MIC ratios can be more reliably accomplished. If Cmax/MIC ratios were optimized early in therapy, it was expected that bacterial eradication would be increased and risk of resistance reduced, that the required therapy duration could be shortened, and that aminoglycoside exposure and toxicity would thereby be minimized because the ototoxicity and nephrotoxicity of aminoglycosides is best correlated with tissue accumulation rather than peak concentrations in serum. The concept of extended-interval dosing of aminoglycosides was first widely advocated for in the early 1990s; by 2000, about 75% of acute care hospitals were routinely using extended-interval regimens and had formal policies for their use. Several clinical studies and many meta-analyses have firmly established the role of extended-interval aminoglycoside regimens, confirming that these regimens are at least as effective as traditional divided-dose regimens with respect to clinical response and bacteriological eradication, with the potential for reduced toxicities. Further advantages of once-daily aminoglycoside dosing include reduction in supply and labor costs and the emergence
of bacterial resistance.

A common method for administration of extended-interval aminoglycoside regimens has been the use of dosing nomograms, among them the well-known Hartford nomogram in which a 7-mg/kg dose is administered at an interval determined by the calculated creatinine clearance. The 7-mg/kg dose specified by the Hartford nomogram was designed to achieve peak plasma concentrations of 20 mg/L in order to provide favorable Cmax/MIC ratios against P. aeruginosa; many other nomograms have also been proposed. These extended-interval regimens continue to be preferred dosing methods for aminoglycosides. However, several points need to kept in mind when using extended-interval regimens or dosing nomograms in critically ill patients. Although nomograms assume that adequate peak concentrations are achieved after administration of doses typically ranging from 5 to 7 mg/kg, many critically ill patients have a significantly increased Vss, which may lead to important reductions in peak plasma concentrations achieved after dosing. In addition, as previously discussed in this chapter, critically ill patients may have either increased or decreased clearance of renally cleared antibiotics, and estimates of renal function in ICU patients are often inaccurate. Because of these potential PK alterations, it cannot be assumed either that extended-interval regimens will produce desired Cmax/MIC ratios or that the aminoglycosides will be cleared from critically ill patients as expected. It is also important to remember that many patients with expected significant PK alterations have not been well represented in clinical studies of extended-interval dosing and/or were excluded from nomogram validation studies. Such patients include those with morbid obesity, pregnant females, patients with ascites or requiring renal replacement therapies, and patients with large total body surface area burns. The other important issue related to use of extended-interval dosing in critically ill patients is that the bacterial pathogens often present in ICU patients have become less susceptible; as bacterial MICs rise, the probability of achieving optimal Cmax/MIC ratios becomes ever more problematic. The combination of increased PK Vss values and increased pathogen MIC values means
that substantially higher doses of aminoglycosides (e.g., tobramycin 10–12 mg/kg or more) will potentially be needed to achieve adequate Cmax/MIC ratios; such doses may also potentially increase toxicity risks and may not be acceptable for routine use despite PK/PD considerations regarding appropriate targets.\textsuperscript{232-234} Whether the AUC\textsubscript{0-24}/MIC ratio may be a better parameter for aminoglycosides in this setting is currently unknown. Careful monitoring of critically ill patients for lack of appropriate response to therapy and evidence of drug toxicities is obviously mandatory during aminoglycoside therapy, regardless of whether extended-interval regimens are used.

The question of whether extended-interval dosing is appropriate for patients receiving renal replacement therapy has been evaluated in several recent studies.\textsuperscript{235-239} The FDA-approved regimen for adults undergoing hemodialysis consists of the administration of gentamicin 1–1.7 mg/kg at the end of each dialysis period. However, administration of relatively low doses does not optimize either Cmax/MIC or AUC\textsubscript{0-24}/MIC ratios and may not be the most appropriate dosing strategy. Results of in vitro and clinical studies of patients requiring hemodialysis suggest that the administration of high, extended interval–like doses (6 mg/kg) of gentamicin to critically ill patients just before hemodialysis sessions allows for achievement of high peak concentrations and maximizes bacterial killing, whereas the subsequently rapid removal by hemodialysis minimizes total drug exposure and risk of toxicity. Administration of aminoglycosides to critically patients by this method has been shown to provide more optimal dosing and achievement of desired PK/PD targets.\textsuperscript{239} Additional study is needed to document the clinical efficacy and safety of high-dose aminoglycosides in this setting, but this does appear to be a viable strategy from a PK/PD perspective.

**High-Dose Fluoroquinolones**

Certain principles of fluoroquinolone PD can readily be applied to the appropriate treatment of infections in critically ill patients. Because fluoroquinolones are concentration-dependent killers with Cmax/MIC or AUC\textsubscript{0-24}/MIC ratios as the key PD parameters, optimizing the PD of the
drug by administering higher doses should allow for more rapid and complete bacterial eradication. Fluoroquinolone PK are somewhat variable in the critically ill, and the drugs are often being used as empirical therapy for infections potentially caused by organisms with reduced fluoroquinolone susceptibility (i.e., higher MICs). Use of high doses (i.e., levofloxacin 750 mg rather than the lower 500-mg dose, ciprofloxacin 400 mg every 8 hours rather than 400 mg every 12 hours) may therefore help minimize the impact of variability in both PK and pathogen susceptibilities and optimize the concentration-dependent PD properties of the drugs in patients with severe infections. Although fluoroquinolones have concentration-dependent killing, excessively high serum concentrations of these agents can be associated with an increased risk of adverse reactions.\textsuperscript{174,240} When a Cmax/MIC of 10 or greater cannot be reached without the use of very high doses because of high pathogen MICs, bacterial eradication becomes a function of concentration and time of exposure on the basis of the AUC\textsubscript{0-24}/MIC ratio.\textsuperscript{174} Fluoroquinolone AUC\textsubscript{0-24}/MIC ratios are often adequate for clinical treatment of infections in ICU patients, even though adequate Cmax/MIC ratios cannot be achieved\textsuperscript{145,152,153}; this is particularly true when critically ill patients have some degree of organ dysfunction because of the potentially decreased drug elimination and increased AUC that may result.

Use of higher fluoroquinolone doses can be particularly beneficial in the treatment of severe infections suspected or documented to be caused by pathogens with intrinsically higher MICs to the drugs (e.g., P. aeruginosa and Acinetobacter spp.). The fluoroquinolones readily penetrate most tissues and fluids of the body, but the use of high doses in the treatment of serious infections should also maximize tissue penetration and more reliably achieve adequate drug concentrations at the infection site. According to the PD properties of the fluoroquinolones, the intensity of dosing and ability to achieve favorable Cmax/MIC or AUC\textsubscript{0-24}/MIC ratios should also minimize the development of resistance. However, of note, many pathogens found in critically ill patients (e.g., most of the enteric gram-negative bacilli, streptococci) are quite susceptible to the fluoroquinolones, and the use of high doses
is not necessary to achieve concentrations adequate for the treatment of most infections. Moreover, note that the foregoing discussion primarily applies to levofloxacin and ciprofloxacin; moxifloxacin doses in excess of 400 mg/day are generally not recommended because of concerns regarding concentration-related prolongation of the electrocardiographic corrected QT (QTc) interval.\textsuperscript{240}

**Dosing of Antifungals**

Fluconazole PK have been reported to be substantially altered in critically ill medical and surgical patients with varying levels of disease severity and normal renal function.\textsuperscript{134,135,241,242} The Vss of fluconazole is predictably increased by about 50\%–100\% compared with that in normal volunteers; these changes are consistent with those expected of a highly hydrophilic drug in critically ill patients.\textsuperscript{241,242} The fluconazole half-life is also generally increased by 50\%–100\% together with the changes in Vss. In contrast, fluconazole clearance appears to be somewhat variable and may be either increased or decreased; this is also consistent with the PK alterations expected in a critically ill population.\textsuperscript{242,243}

According to currently available information from small studies involving heterogeneous patient populations, no definitive general conclusions can be made regarding fluconazole dosing in critically ill patients. Given the concentration-dependent properties of fluconazole and the consistently observed alterations in Vss that have been observed, care must be taken not to underdose fluconazole by administering too small a dose, which will result in low serum concentrations. However, once sufficiently high concentrations are reached, the increased half-life should allow maintenance of high AUCs and adequate drug exposures. This simplistic approach to optimizing fluconazole use in the ICU fails to account for the substantial variability that is typical of hydrophilic, renally cleared drugs in this setting. As discussed earlier in this chapter, allowing for PK variability while maintaining adequate drug exposures can be accomplished by administering aggressive doses. That fluconazole has few important toxicities makes this aggressive approach more acceptable from a
patient safety perspective. Because of the potential for significantly increased half-life, it would also be reasonable to initiate fluconazole therapy with a loading dose, although this approach has not been widely recommended. Future studies focusing specifically on ICU populations are needed to establish definitive recommendations for fluconazole optimization.

According to CLSI susceptibility breakpoints and available clinical data, voriconazole plasma concentrations should be maintained above 2 mg/L over the entire dosing interval because this concentration is also correlated with a favorable f\textsubscript{AUC\textsubscript{0–24}}/MIC for this concentration-dependent drug.\textsuperscript{125,135,169,170,172} However, doses of 3–4 mg/kg every 12 hours in critically ill patients with or without renal impairment may be insufficient to reliably achieve trough concentrations above 2 mg/L for the entire dosing interval.\textsuperscript{244,245} Considering the observed large interpatient variability in healthy volunteers and non-ICU patients\textsuperscript{125} and the possibility of considerable PK variations in the critically ill, it is tempting to consider administering higher-than-normal doses in order to maximize the PD properties of this drug. Given the potential for serious concentration-related toxicities of voriconazole and the potential for many drug-drug interactions, use of higher doses is not recommended until additional clinical studies are available to support this strategy in critically ill patients.\textsuperscript{124-126,133-135,163,164}

Similar to fluconazole and voriconazole, the f\textsubscript{AUC\textsubscript{0–24}}/MIC is the PD parameter most associated with the activity of itraconazole. In a retrospective PK/PD analysis, a total AUC\textsubscript{0–24} greater than 30 mg·hour/L was associated with optimal antifungal efficacy.\textsuperscript{246} However, typical dosing regimens of 200 mg intravenously twice daily for four doses followed by 200 mg intravenously daily may not achieve the targeted f\textsubscript{AUC\textsubscript{0–24}}/MIC greater than 25 in 20% of ICU patients or more.\textsuperscript{246} Higher doses may be required for critically ill patients to achieve better clinical outcomes through dose-optimized administration, but again, specific data related to the use of high-dose itraconazole therapy in this population are lacking.

Echinocandins are concentration-dependent drugs for which f C\textsubscript{max}/MIC and f\textsubscript{AUC\textsubscript{0–24}}/MIC have been correlated with efficacy.
These properties, together with the relatively long half-lives of these agents, support a dosing strategy in which large doses are administered infrequently.\textsuperscript{133,163,172} As with the azoles, use of higher-than-normal doses would seem to be a reasonable option in patients who are not responding favorably to echinocandin therapy. Again, lack of specific data related to the effectiveness of increased doses of echinocandins in severely ill patients is a hindrance to optimizing therapy with these drugs in ICU patients. Lack of a complete understanding of the disposition of echinocandins (and other antifungal agents) in infected tissue sites also contributes to uncertainty regarding whether increased antifungal doses would actually improve clinical efficacy. Currently, use of echinocandin doses higher than those currently indicated in the product labeling is not routinely recommended.

With the increasing prevalence of invasive fungal infections in critically ill populations, optimization of antifungal therapy is critical to achieve favorable clinical outcomes and reduce the risk of toxicity. Some of the more commonly used antifungals, as noted earlier, have been shown to have large intra- and interpatient variations in serum concentrations. Together with the highly dynamic character of critically ill patients, these variations may be more significant and can potentially lead to treatment failure or toxicity. Therapeutic drug monitoring is a useful tool to optimize treatment with the various antifungals, and the role of TDM in antifungal therapy has been reviewed in detail elsewhere.\textsuperscript{124,247,248} Despite the ability to perform TDM in many institutions and increased knowledge of antifungal PK/PD characteristics, optimal use of antifungals remains a challenge to ICU clinicians because of lack of key data in this population.

\textbf{LIMITATIONS OF CLINICAL PK/PD APPLICATIONS IN CRITICALLY ILL}

The severity of infections encountered in the ICU population and the need for adequate Cmax/MIC and AUC\textsubscript{0-24}/MIC ratios are important considerations in severely ill patients. However, there is still much to
learn regarding the direct application of PD principles to the routine
care of critically ill patients. Although it is assumed that the serum
concentrations of most drugs are related to their concentrations in
various tissues, the use of serum Cmax/MIC and AUC\textsubscript{0-24}/MIC ratios
does not always accurately predict tissue concentrations of drugs. A
particularly important limitation of PD principles in the routine care of
ICU patients is that they have not been thoroughly clinically validated in
critically ill populations. Several studies have shown that the PK of
antimicrobials are often significantly altered in critical illness and that
there is a high degree of interpatient (and even intrapatient) variability
in this population.\textsuperscript{13-20} Distribution of antimicrobials to infected tissues
may also be affected by hemodynamic instability and regional or local
changes in perfusion of various organs and tissues. The difficult
combination of severe illness, PK variability, and life-threatening
infections involving potentially drug-resistant pathogens makes the ICU
population a difficult one in which to optimize drug therapy through
appropriate application of PD principles. However, only through using
these principles is optimization of antimicrobial therapy likely to be
achieved in any consistent manner.

A basic limitation inherent in the clinical application of PK/PD
principles is that the data necessary to make informed decisions for
individual patients are simply not available. Optimization of antimicrobial
therapy in individual patients (i.e., estimating patient-specific values for
AUC\textsubscript{0-24}/MIC, Cmax/MIC, and/or f T>MIC) requires that patient-
specific PK and MIC data are able to be used. However, a large
proportion of infections in critically ill patients are empirically treated for
the duration of therapy; no specific pathogen is ever isolated and
therefore the MIC of the pathogen causing the infection in an individual
patient is never known. In addition, TDM is not available for most
antimicrobials being used in clinical practice, and drug concentrations
are rarely actually known. In actual practice, therefore, both PK
parameters and MIC values must be estimated from other sources.
This automatically imposes an inherent handicap on any attempts at
individualization of antimicrobial therapy.

Using mathematical modeling, it is possible to apply PKPD concepts
to clinical practice in an effort to overcome some of these practical limitations. Monte Carlo simulation is used to integrate PK, PD, and MIC data to design rational antimicrobial drug regimens with a high probability of achieving favorable PD targets against organisms that are likely to be encountered in practice. Monte Carlo simulation accounts for the variability in PK values within patient populations as well as the MIC distribution among the pathogens of interest in order to predict antibiotic exposure in entire populations of patients (i.e., MCS modeling simulates the variability in PK parameters that would be seen in a large population of individuals after administration of a specific drug dose or regimen). According to this PK variability, the probability of subsequently achieving specific PK/PD targets can then be determined. In summary, using this program, the probability of obtaining a target exposure that drives a microbiological effect for a given range of MIC values can be calculated. Monte Carlo simulation has become an extremely common method of evaluating the adequacy of existing regimens and designing new regimens that optimize PK/PD exposure in various patient populations. Although MCS is a very valuable tool when applied correctly, many limitations exist. A major consideration for MCS is the PK model used to estimate variability in PK parameters (Vss, clearance, etc.) likely to be encountered in practice. Pharmacokinetic studies of healthy volunteers may be used in MCS, especially when PK data from specific populations such as the critically ill are lacking. However, there is a concern that PK parameters from healthy volunteer studies may not accurately reflect the magnitude or variability in PK alterations within severely ill populations and may overestimate the probabilities of achieving desired PD targets. Another major consideration of PK/PD modeling and MCS is ensuring that appropriate MIC data are used. As much as possible, microbiological data used for MCS must accurately reflect the range and frequency of MICs actually encountered in critically ill patients or, even more ideally, within a specific institution. The role of tissue penetration of antimicrobial and the most appropriate way to include tissue concentrations into MCS modeling are also somewhat controversial and not truly known.

Although useful as a quantitative measure of drug activity or
potency, the MIC itself is also not without several limitations.\textsuperscript{174} The MIC does not mirror true physiological conditions; instead, it is a static measure that does not reflect fluctuating drug concentrations typically observed during the administering of many doses of a drug regimen. Because the MIC measures only inhibition of growth, it does not reflect the rate at which bacteria are actually killed by bactericidal agents. Furthermore, the MIC only quantifies net growth over an 18- to 24-hour observation period. Killing and regrowth may well occur during this period as long as the net growth is zero. Finally, the MIC does not account for the post-antibiotic effects of antibiotics.\textsuperscript{174}

As previously discussed in this chapter, estimates of organ function are imprecise and pose another limitation to applying PK/PD principles in the clinical setting. Assessments of renal and hepatic function and their effects on drug clearance within individual patients are potentially quite inaccurate. Related alterations in other PK parameters such as Vss, protein binding, and half-life are also difficult to estimate, and it can be quite difficult to individualize drug dosing with any precision.

Although the science and practice of PD has made significant progress during the past 30 years and clinical outcomes have undoubtedly been improved through rational application of PK/PD principles, the current state of the art is still actually quite crude. It is currently not possible to fully account for factors such as age, comorbidities, immune function, severity of illness, changes in pathophysiology, and affected PK parameters over time during therapy, yet these and other factors are known to influence patient outcomes in the treatment of infections. Characterization and application of PD parameters that primarily consider only PK and MIC variables obviously lacks a degree of sophistication and highlights how much there is yet to learn regarding how to “optimize” antimicrobial therapy in order to achieve the best possible patient outcomes. Indeed, it has been shown that predicting patient outcomes on the basis of population-based PK/PD parameters is difficult at best and does not accurately predict clinical outcomes in individual patients.\textsuperscript{251}

Finally, it is important to recognize that most of what is known and recommended regarding antimicrobial PD targets has been derived
from in vitro models, in vivo animal models, simulation modeling using techniques such as MCS, and retrospective data from humans. There are still relatively few prospective studies that were specifically conducted to validate PK/PD targets and to test whether the application of PD principles actually results in the desired outcomes, and until recently, well-designed prospective, randomized, controlled trials of the validity of PD principles were (and still are) almost nonexistent. There is clearly a need for additional prospective studies designed to specifically validate the PK/PD principles that are currently being applied to individual patients.

**SUMMARY**

Antimicrobial treatment of critically ill patients remains a significant challenge to clinicians. Many factors, over which clinicians may have little control, may influence the response of an individual patient to antimicrobial therapy; however, optimization of antimicrobial therapy through appropriate drug selection and dosing is one area in which clinicians can make an important difference. Optimization of antimicrobial therapy remains a high priority in the treatment of critically ill patients and requires that drugs be dosed in a manner that maximizes their pharmacologic activity while minimizing the risk of adverse effects and toxicities.

A wide variety of physiological alterations may occur in critically ill patients, many of which have the ability to significantly affect the PK/PD properties of drugs used in this patient population. Clinicians working with patients in the ICU must have a good working knowledge of many issues related to antimicrobial therapy: spectrum of activity of antimicrobials, potential PK alterations present in critically ill patients, how these alterations are likely to affect various types of antimicrobials, the PD properties of the drugs and how these are also likely to be affected in these patients, and how to appropriately apply knowledge of specific PK/PD targets to choose appropriate drugs and regimens that will provide favorable clinical outcomes. Understanding the rationale and limitations related to current clinical applications of
antimicrobial PK/PD properties is also important with respect to the ability of clinicians to optimize antimicrobial use in ICU patients. Although appropriate application of these concepts will likely always remain a significant challenge, PK/PD principles also provide valuable tools by which clinicians can make significant improvements in the care and therapeutic outcomes of the patients they serve.

LEARNING OBJECTIVES

1. Compare and contrast various platforms used to provide data regarding the identity and susceptibility of infecting pathogens.

2. Evaluate the benefits and limitations of rapid diagnostic tests used for infectious diseases.

3. Outline how rapid diagnostic tests should be used to optimize patient outcomes and return on investment.

INTRODUCTION
An ever-important area of infectious diseases in the critical care setting remains identifying infecting microorganisms and determining antimicrobial susceptibility profiles in order to swiftly initiate appropriate antimicrobial therapy. However, the timely selection of an appropriate antibiotic continues to be a challenge for clinicians, especially for patients in the intensive care setting, where a delay of minutes can profoundly affect outcomes. Various studies have shown the significance of promptly administering appropriate antibiotics on survival in patients with high acuity.\textsuperscript{1-3} Methods for culture and susceptibility testing remain suboptimal with respect to the timeliness of data availability. This delay leaves the clinician without critical information and places the patient at risk of suboptimal antimicrobial therapy. Conversely, de-escalation of antibiotics may be needlessly postponed without timely knowledge of the pathogen’s identity and susceptibility, leading to overuse of broad-spectrum agents. Fortunately, advances in technology have presented substantial advances in rapid microbiological diagnostic testing. Various tests have been approved that can now provide vital data within hours rather than days and hold the promise of the decreasing mortality, length of hospital stay, and hospital costs that are associated with managing infectious processes.\textsuperscript{4}

**DIAGNOSTIC TESTS AVAILABLE FOR USE IN INFECTIOUS DISEASES**

**Cultures/Gram Stain**

Culture and in vitro susceptibility testing remain the gold standard for identifying the causative pathogen and characterizing antimicrobial activity. Theoretically, these techniques allow for the detection of as few as 1 CFU of bacteria or fungi per unit of blood. Although culture-based methods for biochemical species identification and susceptibility determination have been used for decades, these techniques are far from ideal. Growing cultures is time- and resource-consuming. It can take more than 18 hours to get adequate bacterial growth from a
specimen to use in subsequent biochemical tests. The time to detection of a microbe is considerably longer for some slow-growing bacteria and fungi.\textsuperscript{5} Furthermore, the time required to detect the presence of a pathogen in a specimen can be prolonged when the amount of microbe in the collected specimen is low or if the patient has previously been exposed to antimicrobials. Another limitation of culture-based detection methods is that they can only detect viable organisms. Unfortunately, culture-based methods cannot identify cellular components such as antigens or genetic fragments that are released after cell lysis. In addition, even though blood is the most common specimen used for culture, circulation of viable organisms in the blood often does not consistently occur, which limits the sensitivity of these tests. In total, all of these limitations can result in delays in detecting and identifying a pathogen and adversely affect decisions regarding antimicrobial use.\textsuperscript{5}

Despite their drawbacks, culture and susceptibility testing continue to serve as first line for identifying and characterizing infectious etiologies owing to the familiarity with the techniques and the relatively low cost associated with these tests.\textsuperscript{6-9} As such, culture-based methods continue to be the standard against which new rapid detection tests are compared. A primary value of cultures is that they provide the microbial growth that is used in determining in vitro susceptibilities and nucleic acid testing. Although in vitro susceptibility testing has its own problems, these data continue to be used to direct patient care, construct antibiograms, and guide antibiotic selection and dosing decisions on the basis of optimizing pharmacodynamic parameters.

**Nucleic Acid Testing**

Decreasing the time in identifying an organism significantly decreases mortality and improves patient outcomes. As mentioned, culture and susceptibility, although widely used, are less than optimal, especially in critically ill patients because of the delayed time to obtaining results. For the past several years, the availability of rapid tests for organism detection has increased.\textsuperscript{9} Examples of tests include those that are based on pathogen lysis, nucleic acid extraction and purification,
nucleic acid amplification, and identification. Various methods to accomplish these tasks have been evaluated, including pathogen-specific assays for targeting species-specific genes, broad-range assays that target genomic sequences, and multiplex polymerase chain reaction (PCR) that focuses on species-specific targets of different organisms. Some of these tests are even intended to detect genes associated with antimicrobial resistance such as mecA in staphylococci or vanA and vanB in enterococci. Currently, many of these tests are used only as a complement to cultures, especially in serious clinical situations. The drawback of this approach is that the tests fail to overcome the technical and sensitivity issues of cultures. Some nucleic acid tests, however, are considered first line for the diagnosis of pathogens such as hepatitis C virus, enteroviruses, Bordetella pertussis, herpes simplex virus (in the setting of herpes encephalitis), and Chlamydia trachomatis.

Historically, use of nucleic acid testing has been limited owing to cost, technical complexity, limited applicability, and the need to determine antimicrobial susceptibility after pathogen identification. However, as test robustness continues to improve and isothermal methods are developed, these technologies may eventually supplant culture as the gold standard for pathogen identification.

The primary limitations associated with the current generation of nucleic acid tests predominantly include the inability to assess antimicrobial susceptibility, complexity, and ability to differentiate between viable and non-viable organisms. Although tests capable of detecting broad arrays of pathogens may be of clinical value, their use may be limited because of the higher risk of contamination owing to the many steps involved in processing specimens. Furthermore, although many of these tests have quick turnaround times, actual timing may be longer because of issues such as transportation of specimens and availability of staff.

One improvement already developed and implemented in nucleic acid testing is the use of nanoparticle probe technology. This technology improves specificity for both nucleic acid and protein detection. Nanosphere has developed the Verigene system. This
system is a novel, multiplex platform that allows for the screening of a sample directly from positive culture medium. Following automated nucleic acid extraction and PCR amplification, the test uses nanoparticle probe technology resulting in target hybridization. The total run time post-inoculation is about 2.5 hours.\textsuperscript{13-15} The gram-positive blood culture (BC-GP) nucleic acid test targets 12 genus- or species-specific targets and meca and vanA/B genes (Table 13.1). The sensitivity and specificity for the various targets are 92.6\%–100\% and 95.4\%–100\%, respectively.\textsuperscript{16} The gram-negative blood culture (BC-GN) test is approved for eight genus- or species-specific targets and six resistance genes, including the extended-spectrum $\beta$-lactamase CTX-M and the carbapenemases IMP, KPC, NDM, OXA, and VIM (www.nanosphere.us/products/gram-negative-blood-culture-test). The percent agreement with this assay and routine methods for identifying and detecting resistance markers was 97.4\% and 92.3\%, respectively.\textsuperscript{13} Although the tests perform well in monomicrobial cultures, test performance declines in the presence of polymicrobial cultures. Another limitation of the assay is its inability to associate a resistance determinate with a particular organism in a polymicrobial culture.

Several studies have assessed the impact of receipt of data from the Verigene test system compared with routine methods. On average, identification results are available 30–40 hours earlier with the Verigene system and susceptibility information 40–50 hours earlier. When acted on in a timely manner, these data can significantly and positively affect treatment decisions. In one study, when results from the Verigene system were acted on by a critical care/infectious diseases pharmacist, the time to receipt of appropriate antibiotic therapy was decreased by 23.4 hours, length of hospitalization was 21.7 days shorter, and hospital costs were $60,729 lower.

**Polymerase Chain Reaction**

Polymerase chain reaction allows for the amplification of a single copy of DNA or DNA fragment. The process involves repeated cycles of heating and cooling in the presence of primers and DNA polymerase, resulting in the amplification of the targeted sequence. Traditionally, results are determined when the presence or absence of the genetic fragment is noted on gel electrophoresis. Polymerase chain reaction can be a highly sensitive method for microbial detection; however, sensitivity is affected by primer and amplicon selection and contamination. Some examples of U.S. Food and Drug Administration (FDA)-cleared PCR-based test systems include the Roche Molecular Systems LightCycler SeptiFast MecA, the BD GeneOhm Cdiff assay, the Cepheid Xpert C. difficile assay, and the Gen-Probe Prodesse ProGastro Cd.

Real-time PCR allows for monitoring of DNA amplification while the assay is in progress rather than at the end of the run. Real-time PCR assays can be used for analysis of genetic polymorphisms, gene
expression, and species identification. The GeneXpert system uses real-time PCR with preparation and detection in a closed compartment to detect methicillin resistance or susceptibility. Depending on the cartridges selected, this system can be used to detect an array of pathogens/resistance determinants, including methicillin-resistant Staphylococcus aureus (MRSA), Clostridium difficile, vanA in enterococci, influenza virus, Norovirus, and resistance in Mycobacterium tuberculosis. For staphylococci, the system can detect mecA and SCCmec genes with a sensitivity of 100% and specificity of 98.6% for methicillin-susceptible S. aureus and a 98.3% sensitivity and 99.4% specificity for MRSA.\textsuperscript{4,18} Results are available within 1 hour.

Broad-range or multiplex PCR provides the ability to rapidly and efficiently amplify different DNA sequences simultaneously using several sets of primers and DNA polymerases. Tests initially use PCR amplification, followed by downstream approaches for identification such as hybridization and sequencing. Examples of multiplex PCR tests currently available include the BD GeneOhm StaphSR assay, the Cepheid Xpert MRSA/SA BC and C. difficile/Epi assays, the Mobidiag Prove-it Sepsis, and the BioFire Diagnostics FilmArray blood culture identification (BCID). The value of these platforms is the rapid, simultaneous screenings of clinical samples for several pathogens. For example, the Prove-it Sepsis can screen for more than 60 bacteria and 13 fungi that produce more than 90% of sepsis-causing pathogens. In addition, resistance markers for genes such as mecA and vanA and vanB can be identified. Results are available in as few as 3 hours with a sensitivity of 95% and specificity of 99%.\textsuperscript{19}

Real-time PCR tests are available to detect the genes encoding for C. difficile toxin B (tcdB) or the toxin regulatory gene (tcdC). Although these tests have sensitivities of 90% and specificities of 96%, their clinical value has been questioned. The positive predictive value (PPV) of these tests varies with the prevalence of disease.\textsuperscript{20} When the prevalence of disease is low (less than 10%), the PPV for an accurate diagnosis is low. Conversely, when the prevalence of disease is high (greater than 20%), the PPV is higher, and the value of the test for making a diagnosis increases. The negative predictive value of the
tests does not change with disease prevalence. Therefore, these tests may be of limited diagnostic value under endemic rates of disease but may be useful in ruling out infection. That the PCR tests detect genes rather than the gene product is another drawback. As a result, individuals colonized with non–toxin-producing strains of C. difficile may be inappropriately identified as being infected. Because it is possible to obtain false-positive results with PCR, clinicians must either use PCR in combination with initial screening using enzyme immunoassays for C. difficile glutamate dehydrogenase or toxins A and B or use PCR in select patients with a high probability of having C. difficile infection. Failure to use the tests judiciously can result in overtreatment of patients and excess cost and can foster antimicrobial resistance in collateral bacterial flora.

Real-time PCR systems greatly reduce the time that meaningful information regarding the causative pathogen and/or expression of resistance is available to clinicians. When appropriately disseminated and interpreted, these data and the ability to rapidly access them can affect antimicrobial use and patient outcome. A study by Carver and colleagues showed that when specimens from patients thought to have S. aureus infections underwent rapid screening with PCR for the mecA gene and data were acted on by an infectious diseases clinical pharmacist, the time to initiating appropriate antibiotic therapy was reduced by 25.4 hours.²¹ Shortening the time to administering appropriate antibiotics may be associated with decreased mortality among patients with sepsis. Additional studies have shown that use of these tests is associated with decreased costs and length of stay owing to a reduction in the use of inappropriate antibiotics and decreased time to appropriate therapy.²²-²⁴ However, if use of these tests is not coupled with an effective implementation strategy, their value for affecting antibiotic use may be limited.²⁵

**Peptide Nucleic Acid with Fluorescence In Situ Hybridization**

Peptide nucleic acid fluorescence in situ hybridization (PNA FISH), a
platform developed by AdvanDx (Wo-burn, MA), uses fluorescently labeled probes with neutral charges that penetrate the cell membrane and cell wall of intact organisms. Peptide nucleic acid probes are DNA mimics that rapidly hybridize to species-specific ribosomal RNA (rRNA) sequences. Bacteria and fungi produce an abundance of highly conserved, species-specific rRNA sequences; therefore, these represent good targets for molecular probes. In addition, because rRNA is naturally amplified in viable cells, targeting rRNA may be accomplished without additional amplification procedures, thus allowing for organism identification without cell rupture and with minimal risk of sample contamination.

A probe is a synthetic oligomer mimicking a DNA or an RNA sequence, and the target is the nucleic acid being detected. Probe detection is accomplished using a fluorescent microscope after hybridization. Results for first-generation tests took about 3 hours to obtain after a positive Gram stain. Newer QuickFISH tests have reduced this time to less than 30 minutes with high sensitivity and specificity. The PNA FISH and QuickFISH systems are available for detecting and differentiating S. aureus and coagulase-negative staphylococci, Enterococcus faecalis and Enterococcus faecium, gram-negative pathogens (i.e., Escherichia coli, Klebsiella pneumoniae, and Pseudomonas aeruginosa), and Candida spp. (i.e., Candida albicans, Candida glabrata, and Candida parapsilosis). In addition, newer XpressFISH assays can identify phenotypic resistance markers such as mecA. The diagnostic accuracy of this platform has been excellent. Rates of agreement between PNA FISH and other diagnostic methods have generally exceeded 95%.26,27

Several studies have determined that PNA FISH testing can help lead to decreased hospital costs, length of stay, and mortality for infections caused by a variety of pathogens, including various gram-positive, gram-negative, and Candida pathogens.11,28-31 In one study, use of PNA FISH aided in detecting coagulase-negative Staphylococcus spp., resulting in decreased hospital length of stay from 6 to 4 days (p<0.05) and decreased hospital costs of about $4,000 per patient.29 Similarly, in a study of 224 patients with hospital-
acquired enterococcal bacteremia, the impact of PNA FISH with subsequent action by an antimicrobial team was examined. E. faecalis was identified 3 days earlier than with conventional culture, and E. faecium was identified 2.3 days earlier. This information resulted in decreased time to initiating appropriate antibiotics (1.3 vs. 3.1 days; p<0.001) and reduction in 30-day mortality (26% vs. 46%; p=0.04). Similar benefits have been reported for PNA FISH for Candida and gram-negative pathogens. Of note, reductions in cost and mortality are only observed when programs are implemented that allow for rapid alteration of antimicrobial therapy based on test results. A delay in response to the resultant information can negate any benefits gained from rapidly acquiring pathogen-identifying data.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) can be used for determining the presence of various pathogens and resistance markers from a variety of sources (e.g., blood, urine, wound). To run, a sample colony is transferred from media to the target slide and covered with a chemical matrix. The target slide is placed in the analyzer and pulsed with a laser, resulting in ionic gas molecules that are accelerated through an electric field and into the time-of-flight analyzer. The rate at which particles travel through the tube and reach the particle detector depends on size. Measurements of particle flight times are converted into mass/velocity values, plotted on a mass spectrogram, and compared with a validated microbe library of results. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry is an extremely versatile system that can be used to aid in detecting a variety of bacterial and fungal species. Run time is quick, with results available within in 1–2 hours. Sensitivities and specificities of up to 98% and greater than 96%, respectively, have been reported with MALDI-TOF MS. The two currently available MALDITOF MS systems are the MALDI Biotyper and the Vitek MS system.
Historically, MALDI-TOF MS was performed on single-colony growth from a subculture of culture bottles. This process meant that results would be delayed until the subculture yielded growth. In an effort to decrease the time to obtain results from MALDI-TOF MS, protocols were developed that screened samples directly from positive culture vials. Although these protocols provided results much faster, several potential pitfalls were associated with this approach. It was noted that material in the blood culture vial such as human proteins, charcoal used to bind antibiotics, and components of the culture broth could produce a background signal that could affect the detection of pathogens.\(^{34-36}\) Furthermore, the type of culture system used (i.e., BACTEC, VersaTREK, or BacT/ALERT) could affect identification rates.\(^{34-36}\) Although problematic, background interference can be minimized by incorporating system-specific processing steps and performing internal validation to develop appropriate interpretative cutoff values.\(^{37}\) Another complication that has been encountered with MALDI-TOF when direct identification from culture vials is used is difficulty identifying pathogens from polymicrobial samples. In this scenario, the proteins from the different pathogens affect the analyzer at overlapping time, thus making differentiation of species-specific peaks difficult.

The cost of acquiring a MALDI-TOF system ranges from about $160,000 to $250,000 and carries a significant annual maintenance cost.\(^{38}\) However, per-test reagent costs can be 200 times less than conventional identification methods. From a clinical standpoint, use of MALDITOF can significantly affect the initiation of appropriate antimicrobials.\(^{39}\) In one study where MALDI-TOF was used sequentially after Gram staining for gram-negative bacteremia, data from MALDI-TOF affected the empiric antimicrobial regimen selected in 35.1% of cases.\(^{40}\) Shortening the time to starting appropriate antibiotic therapy has been associated with decreased lengths of stay and decreased hospital costs.\(^{41-43}\) As with other tests that provide rapid identification of pathogens, benefit is only realized when results are acted on in a timely manner.

ANTIMICROBIAL STEWARDSHIP PROGRAM
IMPLICATIONS

Rapid nucleic acid testing allows antimicrobial stewardship programs to improve patient outcomes and decrease antibiotic use. It is imperative that stewardship teams be thoroughly involved in using these tests and act as educators of the results of each test. The rapid results of the tests are of little value if not acted on in a timely manner. Stewardship teams can help outline which tests should be conducted depending on the prevalence of specific organisms in the hospital, sensitivity and specificity of each test, and price of the test supplies. It is beneficial if hospitals start with a short implementation period to compare factors such as costs of therapy, time to efficient therapy, readmission rate, and mortality. By determining the economic and clinical outcomes of each test, clinicians can appropriately reveal the benefit to patient care.

Regardless of the method used, it is important that the FDA guidelines be followed (GLP [Good Laboratory Practices]) in all steps of infectious disease testing. Standardization of the tests allows for quality assurance in order to increase accuracy. Although many of the newer diagnostic tests are initially more expensive than the traditional cultures, they ultimately may save money and decrease the time to de-escalation from broad-spectrum antibiotics. Each institution should decide whether a particular test would be beneficial in its setting.

Chapter 14
Antimicrobial Resistance in the Critical Care Environment

Andrew M. Roecker, Pharm.D.; and Steven J. Martin, Pharm.D.

LEARNING OBJECTIVES
1. Summarize the epidemiologic concerns associated with antimicrobial resistance, and describe the morbidity and mortality that results from organism resistance.
2. Differentiate the various mechanisms of resistance that occur in gram-positive and gram-negative bacteria.
3. Distinguish the relevant clinical manifestations of individual resistance phenotypes.
4. Explain urgent resistance concerns that are specific to the critical care setting.
5. Design individual patient- and population-based strategies to prevent or minimize resistance.

ABBREVIATIONS IN THIS CHAPTER

CDC Centers for Disease Control and Prevention
INTRODUCTION

Antimicrobial resistance has escalated in recent years. In intensive care units (ICUs) today, patients become infected with organisms for which no antibiotic treatment is effective. This post-antibiotic era in critical illness threatens to reverse significant improvements in survival and outcomes made possible through advanced technology, improved information systems, and novel treatment strategies. Antimicrobial resistance in critically ill patients increases morbidity, mortality, length of hospital stay, and health care costs. Unquestionably, the proliferation and overuse of antimicrobials is the driving factor behind resistance and the resulting adverse outcomes. This chapter will review current issues in antimicrobial resistance associated with critical illness and outline several strategies to reduce the expansion of resistance in individuals and populations.

The prevalence of antimicrobial resistance is increasing throughout the world, especially multidrug-resistant (MDR) bacteria, and this has become a significant threat today to patients in ICUs. Multidrug-resistance is defined as when at least three different classes of
antimicrobials no longer can eradicate the organism. Patients may acquire these bacteria during their stay in the ICU, but many patients have preexisting infection or colonization with resistant or MDR organisms before their entrance in the ICU.\textsuperscript{2,3} Antimicrobial resistance is a barrier to the selection of appropriate antimicrobial therapy for serious infection, such as sepsis, pneumonia, or bloodstream infection.\textsuperscript{4,5} Antimicrobial resistance and the resulting inappropriate initial antimicrobial treatment are important risk factors for mortality, increased duration of mechanical ventilation and ICU stay, higher rates of recurrence of infection, and higher costs.\textsuperscript{6-9}

The annual yearly cost to the U.S. health system alone from antimicrobial resistance has been estimated at $21–$34 billion dollars and may account for more than 8 million additional hospital days.\textsuperscript{10} In the United States, more than 23 million people each year develop infection with organisms that demonstrate antimicrobial resistance, accounting for 23,000 deaths annually.\textsuperscript{11} The cost of care for patients with antimicrobial-resistant organisms is higher than for those with antimicrobial-susceptible organisms by $6,000–$30,000.\textsuperscript{12}

The increased length of hospital stay and increased mortality, together with the excess costs associated with infection by resistant organisms, may be because of a variety of factors that include the patient, organisms, and treatment. The severity of the underlying disease in the patient may be synergistic with infection by resistant organisms, leading to poor outcomes.\textsuperscript{12} For patients infected with resistant organisms, inappropriate treatment, ineffective dosage selection, delayed appropriate therapy, and treatment toxicity may lead to poor outcomes or higher costs.\textsuperscript{12} Box 14.1 highlights important global concerns regarding antimicrobial resistance.

Inappropriate therapy because of antimicrobial resistance causes higher mortality rates in patients with ventilator-associated pneumonia (VAP).\textsuperscript{5} The same poor outcomes have also been observed in patients with bacteremia from methicillin-resistant Staphylococcus aureus (MRSA) and vancomycin-resistant Enterococcus (VRE) bacteremia.\textsuperscript{14,15} Increased mortality has been associated with infections from extended-spectrum β lactamase (ESBL)–producing
Klebsiella pneumoniae.\textsuperscript{16} In a recent study of 2,594 patients with sepsis or septic shock who had positive blood cultures, 788 did not survive, and resistance to cefepime or meropenem, the presence of MDR bacteria, non-abdominal surgery, and prior antibiotic use were identified through logistic regression as being independently associated with the administration of inappropriate antimicrobial treatment leading to death.\textsuperscript{17} Box 14.2 lists antimicrobial resistance threats that may affect patients in the ICU.

Antibiotic exposure to bacteria in sublethal concentrations can promote subsequent resistance. Free radical production in the bacteria stimulated by the presence of antibiotic produces DNA mutations that can lead to protection from the antibiotic to which it was exposed, and often to other antibiotic classes.\textsuperscript{18} Genetic mutations producing antimicrobial resistance are often stable and retained in bacteria even in the absence of ongoing exposure to the antibiotic.\textsuperscript{19}

Bacteria are adaptable to their environment and quickly become tolerant of toxins in order to survive and reproduce. Low levels of genetic resistance may be common in most bacteria for protection against exposure of naturally occurring antibiotics produced by other microorganisms in the environment.\textsuperscript{20} The exchange of genetic material by bacteria leads to the extension of resistant genes from organism to organism. Antibiotic resistance coded for on bacterial chromosomal DNA may also be exchanged among bacteria through mobile genetic elements such as plasmids. Plasmid-acquired resistance is largely driven by antimicrobial exposure.\textsuperscript{18}

---

**Box 14.1. Global Antimicrobial Resistance Concerns\textsuperscript{13}**

- 20\% of people are persistent carriers of S. aureus;
- $3$ billion is the annual health care cost associated with MRSA in the United States;
- 19,000 deaths each year are caused by MRSA in the United States;
• 61% of E. faecium is resistant to vancomycin in the United States;
• 40% of S. pneumoniae strains are resistant to penicillin;
• 50% chance of contracting C. difficile after more than a 4-week hospital stay;
• 30% increase in carbapenem-resistant A. baumannii strains from 1995 to 2004
• 30% resistance to fluoroquinolones in Enterobacter spp.

The proliferation of various resistance genes has been promoted by widespread use of synthetic antimicrobial agents. Further regional or local concentrated drug use, such as through formulary or antimicrobial restriction, further exacerbates resistance through chromosomally mediated mechanisms. The pressure of antimicrobial use can lead to mechanisms of resistance that often convey MDR. Efflux pumps are an example of a resistance mechanism that can often be non-specific conferring resistance to many types of drugs. Horizontal gene transfer, which can spread resistance to several antibiotics in a single step, may also give rise to MDR.

Specific patient risk factors for antimicrobial resistance include prior exposure to antibiotics, prior physical exposure to the health care environment (hospitals, nursing homes, etc.), comorbid conditions such as diabetes mellitus, advancing age, renal insufficiency and uremia, use of corticosteroids and other immunosuppressive medications, and radiation therapy.

Antimicrobial exposure does not occur only during times of infection or suspected infection. Humans use antibiotics extensively at home and in hospitals, in such products as hand sanitizers and household cleaners. Antibiotics are used extensively in animals and agriculture. In the United States, antibiotics are still being given to animals to promote growth. Antibiotics are also sprayed on trees and other vegetation. Thus, resistance concerns in the ICU have their origin well outside the
critical care and hospital setting.

GENERAL ANTIMICROBIAL RESISTANCE MECHANISMS

Antimicrobial resistance occurs by several different and disparate mechanisms. There is intrinsic or innate resistance in which an antimicrobial agent has no inherent activity against a specific pathogen. An example is vancomycin, which has no activity against gram-negative bacteria. Resistance of this type is a class phenomenon, is commonly understood by clinicians, and is not routinely confirmed by clinical laboratory susceptibility testing.\(^{25}\) Most acquired resistance mechanisms can be categorized in general classes, with notable variety and degrees of mutation.

One general resistance class includes genetic mutations encoding for production or overproduction of medication-lysing enzymes. An example of this is production of β-lactamase that will enzymatically metabolize various β-lactam medications before their ability to bind to penicillin-binding proteins (PBPs) and damage the bacteria.\(^{25}\) The PBP is important for the production of peptidoglycan, a key component of the cell wall. Normally, β-lactam antibiotics bind to the PBPs, disabling their ability to form a functional cell wall; the modifications prevent this from occurring. The extent of specificity for β-lactams by β-lactamases has waned over time, such that more problematic β-lactamases like ESBLs and metallo-β-lactamases have become more prevalent and render many more antimicrobials ineffective than earlier enzymes, which inhibited only penicillin or first-generation cephalosporins.\(^{26}\)

Another general resistance class includes genetic mutations that either decrease binding to a specific mechanistic target or altogether change the target-binding site. These result in either suboptimal activity from an antimicrobial that previously inhibited the organism or complete resistance and antimicrobial failure. An example of this would include the meca gene that codes for a change in PBP from PBP2 to PBP2a, resulting in resistance to medications that bind to that target, such as penicillins and cephalosporins.\(^{25}\) Another example occurs in enterococci causing vancomycin resistance by alterations in the binding target from
d-alanine-d-alanine by substituting a d-lactate instead of one of the d-alanines. This alters the binding site and results in drug resistance; it is often coded for by vanA, vanB, or vanD resistance genes.\textsuperscript{27} There also may be mutations to intracellular binding sites, including mutations to DNA gyrase, topoisomerase IV, or genes that methylate ribosomal RNA.\textsuperscript{28}

A third general resistance class is generation of efflux pumps that expel the antimicrobial agent before it reaches its binding site. This mechanism affects medications acting intracellularly.\textsuperscript{25} Macrolides and tetracyclines are examples of agents that are affected by microbial efflux pumps because of their intracellular ribosomal binding targets. \textit{S. aureus} may also produce efflux pumps effective against fluoroquinolones, which helps to explain their lack of activity in treating staphylococcal infections.\textsuperscript{29}

The aforementioned three general resistance mechanisms occur as a result of an acquired genetic mutation. In contrast, microorganisms may pass genetic material through conjugation, transduction, or transformation. This often occurs through plasmid transference from one organism to another. If the genetic material on the plasmid contains resistance information, this mechanism explains the spread of antimicrobial class resistance between different genus and species of organism. The plasmid-transported \textit{qnr} gene has been identified as a proliferation mechanism for fluoroquinolone resistance between bacterial pathogens.\textsuperscript{25,29}

---

\textbf{MAJOR RESISTANCE MECHANISMS IN CRITICAL CARE AREAS}

All of the general resistance mechanisms described earlier occur in critical care patients, and the underlying comorbidities and severity of illness in these patients coupled with antimicrobial resistance often results in poor patient outcomes. Recognition of possible resistance is key to minimizing inappropriate antimicrobial therapy and poor treatment outcomes. Institution- and unit-specific anti-biograms may identify local resistance patterns and help direct empiric drug selection.
These data may also reduce overuse of broad-spectrum antimicrobial agents, reducing drug exposure and focusing activity on likely pathogens. Furthermore, some newer methods of rapidly diagnosing infections, as well as resistance, in critical care patients could greatly assist in timely and accurate use of antimicrobials. Urine antigen testing for Streptococcus pneumoniae and Legionella pneumophila has held utility for patients with diagnoses of community-acquired pneumonia. However, new technology using PCR (polymerase chain reaction), ELISA (enzyme-linked immunoassay)-based and “in situ” hybridization, and direct E-test may supplant traditional culture and susceptibility results for empiric antimicrobial therapy. Currently, some of these modalities are available to assist with catheter-related bloodstream infections, VAP, urinary tract infections, and skin and skin structure infections. Rapid diagnostic tests are useful as adjuncts to culture and susceptibility testing until specificity and sensitivity of the newer tests are better addressed. Ancillary measures of inflammation including C-reactive protein and procalcitonin can also aid in determining infectious versus non-infectious causes.30

**CLINICAL RELEVANCE OF RESISTANCE**

Reducing antimicrobial resistance requires minimizing the use of antimicrobials. During the past decade, advances in technical aspects of patient care and an emphasis on avoidance of nosocomial infection have led to notable decreases in many health care–associated infections (HAIs). The Centers for Disease Control and Prevention’s (CDC’s) HAI Progress Report notes reductions in central line–associated bloodstream infections (46% decrease) and surgical site infections (19% decrease) from 2008 to 2013.31 Also reported were decreases in hospital-onset MRSA bacteremia (8% decrease) and hospital-onset Clostridium difficile infections (10% decrease) from 2011 to 2013.31 Nonetheless, infection is still common in critical illness, and several antibiotic resistance issues are a concern in ICUs. The CDC published Antibiotic Resistance Threats in the United States, many of which will have direct application in the critical care environment (Box
Urgent Threats with Concern in Critical Care

Carbapenem-Resistant Enterobacteriaceae

Enterobacteriaceae are gram-negative bacilli typically found in the gastrointestinal (GI) tract. The most commonly reported Enterobacteriaceae associated with infection are Escherichia coli, K. pneumoniae, and Enterobacter spp. Enterobacteriaceae cause an estimated 140,000 HAIs each year, with many in critically ill patients.

The increasing prevalence of ESBL infections has forced the expanded use of carbapenems, driving carbapenem-resistant Enterobacteriaceae (CRE). The percentage of total Enterobacteriaceae that were carbapenem resistant has increased to 4.2% in 2012 from 1.2% in 2001.

Hydrolyzing carbapenemases are responsible for CRE resistance. K. pneumoniae carbapenemase and VIM (Verona integrin-encoded metallo-β-lactamase) are the primary enzymes involved. K. pneumoniae carbapenemase produces resistance to all cephalosporins, aztreonam, and currently available β-lactamase inhibitors (avibactam, clavulanate, and tazobactam). K. pneumoniae carbapenemase is spread horizontally through plasmids and has also been identified in E. coli, Klebsiella oxytoca, Enterobacter, and Serratia.

Infection with CRE has been associated with mortality rates of more than 40%, with most being from carbapenem-resistant K. pneumoniae (85.2%).

Carbapenem-resistant Enterobacteriaceae bacteremia is associated with a 50% mortality rate. Polymyxins such as colistin as well as tigecycline and aminoglycosides may retain activity against K. pneumoniae carbapenemase–producing organisms. Recent studies suggest that combinations of colistin-polymyxin B or tigecycline with a carbapenem lead to less mortality than monotherapy of colistin-polymyxin B or tigecycline for the treatment of K. pneumoniae.
Serious Threats with Concern in Critical Care

Acinetobacter spp.
Multidrug-resistant Acinetobacter infections are classified as a serious threat by the CDC and are associated with bacteremia, pneumonia, urinary tract infection, and surgical site infections among critically ill populations. Multidrug-resistant Acinetobacter baumannii may be defined as resistant to three or more classes of antibiotics. Acinetobacter is responsible for an estimated 12,000 infections yearly in the United States, with 61% (7,300) of those being classified as MDR. Multidrug-resistant Acinetobacter infections result in 500 deaths annually. Acinetobacter causes about 2% of all HAIs reported to the CDC but 7% of the infections reported in critically ill patients on mechanical ventilation.

Threats of Concern
• Vancomycin-resistant S. aureus (VRSA)

Resistance is usually acquired by A. baumannii through plasmids. Multidrug-resistant mechanisms include target site modification, enzymatic drug inactivation, efflux pumps, and porin channel modification. Multidrug-resistant A. baumannii can be difficult to treat because it is often resistant to many or, in some cases, all commercially available classes of antibiotics, including carbapenems, thereby leading to the need for more unconventional treatment combinations and more research into therapeutic options for those infections. Colistin or other polymyxins in combination with other agents such as ampicillin/sulbactam, aminoglycosides, carbapenems, and rifampin has been used with mixed success to treat infections from MDR organisms. More recent data may also suggest that use of intravenous minocycline provides utility in treating resistant A. baumannii and other MDR organisms.

Candida spp.

About 46,000 health care–associated Candida infections occur annually in hospitalized patients in the United States. Fluconazole-resistant Candida infections result in 3,400 infections and 220 deaths and are considered a serious threat by the CDC. Drug-resistant Candida bloodstream infections lead to about 30% mortality during hospitalization. Candida albicans remains the most common fungal pathogen, but resistance is common in other Candida spp. Candida are increasingly resistant to first- and second-line therapies such as azoles (fluconazole) and echinocandins (caspofungin, micafungin, anidulafungin). Systemic candidiasis may increase hospital length of stay by 3–13 days and add $6,000–$29,000 in direct costs. Critical illness is a risk factor for systemic fungal infection, and drug-resistant
Candidemia leads to about a 30% mortality rate. Clinical laboratory susceptibility testing of fungi is still uncommon in the United States. The clinician must recognize potential inherent resistance issues among non-albicans Candida, as well as local resistance concerns among C. albicans. Although C. albicans drug resistance remains low, C. glabrata and C. krusei may produce drug-resistant candidemia. Induction of efflux pumps is the most common acquired azole resistance mechanism for Candida spp. Echinocandins retain excellent activity against most Candida spp. and should be considered first-line therapy for the treatment of candidemia. Candida parapsilosis and Candida guilliermondii are inherently resistant to echinocandins, and C. albicans, C. tropicalis, C. krusei, C. glabrata, and C. lusitaniae may acquire echinocandin resistance through genetic mutation. Critically ill patients whose echinocandin therapy for candidemia fails should undergo susceptibility testing to determine optimal drug treatment.

**ESBL-Producing Enterobacteriaceae**

Extended-spectrum β-lactamase–producing Enterobacteriaceae infections constitute 19% (26,000) of all infections caused by Enterobacteriaceae, and K. pneumoniae and E. coli are the most common pathogens (17,000 and 9,000 cases, respectively). Cephalosporin overuse is commonly cited as the primary cause of the proliferation of ESBLs. Extended-spectrum β-lactamase–producing Enterobacteriaceae cause 1,700 deaths each year. Bacteremia from an ESBL-producing pathogen produces a 57% higher mortality rate than non-ESBL pathogens. The cost of infection with an ESBL-producing Enterobacteriaceae pathogen is more than $40,000. Extended-spectrum β-lactamase–producing Enterobacteriaceae are resistant to most extended-spectrum penicillins and cephalosporins, but they remain susceptible to carbapenems.

The prevalence of ESBL-producing Enterobacteriaceae is less than 10% across all infection types, with more isolates identified in intra-abdominal and urinary tract infections than pneumonia or bacteremia.
Critically ill patients are at high risk of ESBL-producing organisms because they commonly have invasive indwelling devices such as central venous catheters, urinary catheters, and endotracheal tubes. Prior exposure to the health care or hospital setting and prior antibiotic therapy increase the risk of ESBL production.

Almost all β-lactams are hydrolyzed by ESBLs, leaving carbapenems as the most active agents of the class against these organisms. Piperacillin/tazobactam may also remain active in infections with lower organism burden when the minimum inhibitory concentration (MIC) is 16 mcg/mL or less.

Cefepime in standard doses may be effective for ESBL-producing Enterobacteriaceae when the MIC for the organism is 2 mcg/mL or less, although most clinical laboratories routinely list it as resistant when an ESBL is suspected. Higher cefepime doses may be considered for MICs in the 4- to 8-mcg/mL range.

Ceftolozane/tazobactam, one of the first cephalosporin β-lactamase inhibitor combinations available, could provide some additional activity against ESBL-producing pathogens. The combination maintains activity against some ESBL-producing E. coli, but it may have no activity in ESBL-producing Klebsiella spp. where carbapenemases may be present. Its specific place in therapy is still to be determined, but it is an option for consideration when MDR occurs, particularly within the critical care areas.

Enterococcus spp.

Enterococci are gram-positive cocci common to the GI tract. In the critically ill population, enterococci are common pathogens in mixed bacteria-intra-abdominal infections, urinary tract infections, surgical site and wound infections, and less commonly bloodstream infections. Vancomycin-resistant Enterococcus is responsible for about 20,000 infections and 1,300 deaths per year. Almost one-third of bloodstream, urinary tract, and surgical site enterococcal infections are VRE. The most common resistant species of VRE is Enterococcus faecium, which accounts for half of the cases and deaths associated
with vancomycin resistance. The rate of vancomycin-resistant E. faecium is much higher than that of vancomycin-resistant Enterococcus faecalis.

Resistance to vancomycin in enterococci is mediated by binding site modifications in the terminal d-alanine that results in decreased vancomycin binding. The most common phenotypes of VRE are vanA and vanB. vanA produces broad resistance in vancomycin and teicoplanin, whereas vanB produces resistance to vancomycin but not teicoplanin. These resistance genes are carried on plasmids and can be shared to other gram-positive bacteria including S. aureus.

Therapeutic options for VRE infection are oxazolidinone (linezolid or tedizolid), with other lipoglycopeptides such as daptomycin, telavancin, dalbavancin, or oritavancin possibly retaining activity. Fosfomycin and nitrofurantoin may be effective in treating urinary tract infection, but they are only available for oral administration in the United States.

**Pseudomonas aeruginosa**

P. aeruginosa is a nonfermenting, aerobic gram-negative bacilli that is responsible for pneumonia, bloodstream infections, urinary tract infections, and surgical site infections in critical illness. Multidrug resistance occurs in 13% of pseudomonal HAIs. Multidrug resistance in P. aeruginosa is defined as resistant to three or more drug classes. Surveillance data analyses from the European Antimicrobial Resistance Surveillance Network reported that resistance rates for aminoglycosides, carbapenems, quinolones, and ceftazidime were 0%–51.9%, 9%–50.5%, 7.2%–51.9%, and 4%–48.5%, respectively. Overall, 18% of isolates were recorded as being MDR. Multidrug-resistant organisms are more prevalent in critically ill populations than in populations in other hospital wards.

Many resistance mechanisms are responsible for MDR P. aeruginosa. The organism produces chromosomally mediated AmpC β-lactamase and can obtain ESBLs and carbapenemases, such as metallo-β-lactamases. Fluoroquinolone resistance is chromosomally mediated through DNA gyrase mutations. P. aeruginosa may also
produce aminoglycoside-modifying enzymes and can modify porins and express efflux pumps to reduce drug entry into the cell.\textsuperscript{51}

Combination therapy is recommended for empiric treatment to improve the likelihood of appropriate initial therapy. Although described in vitro, synergy between different classes of antibiotics against MDR \textit{P. aeruginosa} is not considered an in vivo phenomenon. Combinations could include carbapenems or antipseudomonal β-lactams with aminoglycosides or colistin-polymyxin. Once susceptibility data are available, streamlining therapy with one effective agent is appropriate, although monotherapy with aminoglycosides may lead to drug resistance.

\textbf{S. aureus}

\textit{S. aureus} is a gram-positive cocci that is a common pathogen in HAI. The organisms are commensal on skin and are introduced into sterile spaces through breaks in the dermal layer, such as with indwelling vascular catheters, or surgical incision. Methicillin resistance in \textit{S. aureus} occurs through the chromosomally mediated production of the transpeptidase PBP2a. The PBP2a transpeptidase is encoded by the gene \textit{mecA}, which is located on the staphylococcal cassette chromosome. The PBP2a transpeptidase has an altered binding affinity for β-lactams such that almost all β-lactams are rendered ineffective against MRSA.\textsuperscript{52} Although methicillin is no longer used, MRSA is also resistant to all other semisynthetic penicillins, including oxacillin, nafcillin, and dicloxacillin.

Despite declining rates in recent years, invasive MRSA infections number 80,461 per year in the United States, resulting in 11,285 deaths.\textsuperscript{11} Methicillin-resistant \textit{S. aureus} became a clinical concern in the 1980s and 1990s, and the prevalence of MRSA among \textit{S. aureus} in the United States today is about 24%.\textsuperscript{11} Risk factors for MRSA include recent prior hospitalization or interaction with the health care setting, residence in a nursing home or long-term care facility, intravenous drug use, and hemodialysis.\textsuperscript{52} Community-acquired MRSA became a health concern in the 1990s and is defined as occurring in individuals who did
not have the risk factors described earlier. It commonly produces skin and skin-structure infections. The terms health care–associated MRSA and community-associated MRSA became common to describe these two uniquely different infections. Community-associated MRSA is often susceptible to clindamycin, tetracycline, aminoglycosides, and fluoroquinolones, whereas health care–associated MRSA is typically resistant to those agents.52,53

Vancomycin remains the drug of choice for empiric treatment, but MICs to vancomycin have been increasing during the past decade. Recent data suggest that MRSA with a vancomycin MIC of 2 mcg/mL occurs in 5.1% of patients and is an independent predictor of mortality.54 The MIC susceptibility breakpoint to determine vancomycin susceptibility for S. aureus was 4 mcg/mL, but in recent years, it has been lowered to 2 mcg/mL because of the clinical failures in patients with isolates with vancomycin MICs greater than 1 mcg/mL.52

Vancomycin-resistant S. aureus has been identified in the United States, but it remains uncommon. vanA transfer from VRE is responsible for vancomycin-resistant S. aureus. Vancomycin-intermediate S. aureus are organisms with a vancomycin MIC of 4 or 8 mcg/mL. Vancomycin-intermediate S. aureus may be constitutive (heterogeneous). When selective pressure occurs in the clinical setting, the organism induces modifications to the bacterial cell wall that reduce the ability of vancomycin to diffuse into the cell wall. Vancomycin susceptibility can return to the organism once the selective pressure is removed. Many antibiotics retain activity against vancomycin-intermediate S. aureus, including linezolid and tedizolid, tigecycline, minocycline, telavancin, oritavancin, and dalbavancin.52 Heterogeneous vancomycin-intermediate S. aureus has created a potential clinical concern with microbiologic susceptibility testing. The organism may be interpreted as susceptible to vancomycin when tested in vitro, but the portion of the inoculum that is not inhibited by vancomycin could selectively grow and lead to vancomycin treatment failure.

Use of vancomycin to maintain serum trough concentrations at 15–20 mcg/mL has been recommended for MRSA infection, but the data are mixed on the success of this strategy and the potential for
nephrotoxicity from exposure to high vancomycin concentrations.\textsuperscript{52} Alternatives to vancomycin include linezolid, tedizolid, daptomycin, telavancin, oritavancin, dalbavancin, tigecycline, and ceftaroline. Linezolid may be an effective alternative to vancomycin for MRSA infections when the vancomycin MIC is greater than 1 mcg/mL, especially when the infection is in the lung, meninges, or other compartments into which vancomycin poorly diffuses.\textsuperscript{52}

**GENERAL STRATEGIES TO MINIMIZE ANTIBIOTIC RESISTANCE**

Minimizing antimicrobial resistance is possible using multifaceted strategies that are directed at population-based and individual patient-based interventions. The Infectious Diseases Society of America/Society for Healthcare Epidemiology of America guidelines to minimize resistance recommend that all hospitals form antimicrobial steward-ship teams.\textsuperscript{40} Antimicrobial stewardship programs improve patient care and reduce costs.

Appropriate culture techniques leading to high-quality laboratory data allow for streamlining of antimicrobial therapy to a narrower-spectrum agent or discontinuation of antimicrobials in patients without infection. Hospital-acquired pneumonia (HAP) and VAP are examples of the need for high-quality culture techniques. Hospital-acquired pneumonia/VAP accounts for around 50\% of antibiotic use in the hospital, yet clinical signs and symptoms are poor markers of disease.\textsuperscript{55} The American Thoracic Society guidelines recommend using quantitative cultures from deep in the respiratory tract because a minority of patients (about 40\%) who present with signs and symptoms of VAP actually have pneumonia when this technique is used.\textsuperscript{56} Rapid diagnostic measures either addressing general inflammatory measures (C-reactive protein or procalcitonin) or pathogen- and resistance-specific testing could lead to more timely initiation or discontinuation of antimicrobial agents for HAP/VAP.

Antibiotics should be discontinued if cultures are negative and infection is unlikely. There are an increasing number of studies
suggesting that antibiotics initiated empirically for suspected infection, such as HAP/VAP, can be safely discontinued in patients with negative cultures and resolving clinical signs.57-62 For patients in whom microbiologic cultures have identified an organism, streamlining antibiotics to narrower-spectrum agents is recommended to reduce unnecessary exposure of antimicrobial agents.63-65

The optimal direction of therapy for most infections in the critically ill population has not been determined. Increasingly, data suggest shorter treatment duration is associated with infection resolution, minimizing unnecessary antibiotic exposure. For HAP/VAP, short-duration therapy (3–7 days) has been shown to be as effective as long-duration therapy (14–15 days) in recent trials, with the exception of infections caused by P. aeruginosa.57-59 Shorter-duration therapy has also been associated with fewer relapses with resistant organisms.66,67 Seven days of therapy may be adequate for bloodstream infections caused by selected pathogens, but organisms such as S. aureus do not respond well to short-duration therapy.62,68

Inappropriate antimicrobial dosing in critically ill patients may lead to suboptimal drug concentrations for organism eradication. Infections in spaces that have poor drug penetration, such as meninges or lung, as well as pharmacokinetic changes that occur in critical illness, such as increased distribution volume, may lead to ineffective therapy. Drug doses should be adjusted on the basis of individual pharmacodynamic targets for drug and organism and pharmacokinetic parameters to meet those targets at the infection site.

Use of local antibiograms is recommended for empiric antibiotic selection to allow the use of narrower-spectrum agents in patients who are not at high risk of infection with pathogens such as P. aeruginosa and MRSA and should be based on local organism patterns.55,65 Antibiograms should routinely be updated, at a minimum, twice annually. Box 14.3 summarizes efforts to reduce antimicrobial resistance in critical care environments.
Care Environments$^{31,55,63-65}$

- Use high-quality culture techniques for blood, sputum, urine, and wound cultures
- Use rapid diagnostics for isolate identification and resistance
- De-escalate or discontinue broad-spectrum antimicrobials when information is available to do so
- Use therapy durations appropriate for specific infection and causative pathogen, minimizing lengthy durations where data suggest them unnecessary
- Use appropriate patient-specific parameters to avoid under- and overdosing of antimicrobials
- Use updated local antibiogram information for empiric antimicrobial dosing and protocol development

CONCLUSION

Other strategies to minimize resistance, such as antibiotic cycling and formulary restrictions, remain largely unproven. The focus of antimicrobial stewardship programs should be to reduce overall antibiotic use through the strategies outlined earlier.

Antimicrobial resistance remains a problem in managing infection in the critically ill population and leads to excessive morbidity and mortality. Despite continuing advances in drug design, microorganisms have evolved genetically to demonstrate a dynamic arsenal of mechanisms to reduce or eliminate the effectiveness of antimicrobial agents. Clinicians must identify risk factors for resistance in patients and engage in broad, population-based strategies to reduce the likelihood of resistance generation or spread of resistance in local ICUs. Early identification of pathogens and their resistance patterns will help target appropriate and effective therapy, resulting in improved outcomes.

LEARNING OBJECTIVES

1. Construct an initial resuscitation pathway that includes quantitative resuscitation for patients with severe sepsis or septic shock.

2. Design an appropriate antimicrobial treatment strategy for adult patients with severe sepsis or septic shock that combines initial broad-spectrum therapies and subsequent de-escalation of therapy.

3. Evaluate the risks and benefits of volume resuscitation with crystalloids and colloids for patients with hemodynamic instability as the result of severe sepsis or septic shock.

4. Devise a treatment strategy for the hemodynamic management and monitoring of patients with severe sepsis or septic shock.

5. Distinguish scenarios in which the use of corticosteroids as an adjunct for septic shock is supported by the 2012 Surviving Sepsis Campaign (SSC) guidelines.

6. Develop a treatment pathway for the care of patients with severe sepsis or septic shock that incorporates the 2012 SSC guideline care bundles, new data since publication of the last guidelines, and National Quality Forum recommendations.
INTRODUCTION

Severe sepsis and septic shock are extreme conditions on the systemic infection disease continuum. In sepsis, an infecting pathogen elicits a systemic inflammatory response, which may be complicated by end-organ dysfunction (severe sepsis). Septic shock is characterized by acute circulatory failure leading to ineffective tissue perfusion and cellular hypoxia and is typically defined as arterial hypo-tension unresponsive to fluid administration.¹

Overall, the in-hospital mortality associated with severe sepsis and septic shock is around 25%,² and mortality at 2 years is around 45%.³ Classification of sepsis stage is important because mortality ranges from 15% with sepsis to as high as 70% with septic shock and multiorgan failure.⁴ Prompt initiation of therapies is of utmost importance because patients may quickly progress through the stages of sepsis from systemic inflammatory response syndrome to septic shock. Further complicating matters is the fact that sepsis is common (annual U.S. incidence greater than 890,000), increasing in incidence
(by about 13% per year), and costly, with annual costs in the United States exceeding $24 billion.\textsuperscript{2} Septic shock is the most commonly encountered shock type, accounting for 62% of all cases of shock requiring vasopressors.\textsuperscript{5} Fortunately, data evaluations suggest that outcomes in patients with severe sepsis and septic shock are improved through therapeutic intervention.\textsuperscript{6} This should serve as a call to action for intensive care unit (ICU) practitioners.

The Surviving Sepsis Campaign (SSC), a joint collaboration between the Society of Critical Care Medicine and the European Society of Intensive Care Medicine, has published three iterations of international guidelines for the treatment of patients with severe sepsis and septic shock. The 2012 SSC guidelines, published in early 2013, were sponsored or endorsed by 30 international organizations\textsuperscript{7}; a portion of the pharmacologic-related SSC recommendations is summarized in Box 15.1. Important differences between the 2008 and the 2012 SSC guideline recommendations can be found in Table 15.1. Translating the literature and treatment principles described in these guidelines to bedside care while incorporating an assessment of patient-specific data is necessary to design a comprehensive pharmacotherapeutic care plan for the patient with severe sepsis or septic shock.

**PATHOPHYSIOLOGY**

Severe sepsis and septic shock involve complex interactions between an infecting pathogen and the host inflammatory, immune, and coagulation response (Figure 15.1). The pattern recognition (e.g., toll-like) receptors on innate immune system cells recognize specific molecules present in microorganisms and signal the release of nuclear factor kappa B (NF-κB), which leads to the transcription of both proinflammatory cytokines (e.g., interleukin [IL]-1β, IL-6, tumor necrosis factor α) and anti-inflammatory cytokines (e.g., IL-10). The proinflammatory cytokines activate neutrophils and endothelial cells, leading to an increased expression of inducible nitric oxide synthase. Concomitantly, the coagulation cascade is activated by tissue factor presented by monocytes, and anticoagulant pathways are depressed;
this leads to microvascular thrombosis and impaired tissue perfusion (Figure 15.2). Although target-specific therapies are not currently in clinical use for sepsis, knowledge of these factors may lead to new therapeutic modalities.

Hypotension develops through inappropriate activation of vasodilatory mechanisms (increased nitric oxide synthesis) and failure of vasoconstrictive pathways (activation of ATP-dependent potassium channels in vascular smooth muscle cells and vasopressin deficiency), resulting in a vasodilatory shock. In addition, blood flow is inappropriately dispersed at the organ level or in the microcirculation (shunting), leading to distributive shock. Vascular endothelial cell injury leads to shedding of the endothelial glycocalyx and loss of tight junctions between endothelial cells, resulting in capillary fluid leak and a decrease in cardiac preload. Venous dilation further exacerbates the decrease in cardiac preload and worsens hypotension. Tissue oxygen delivery may be further impaired through a decrease in cardiac output from myocardial stunting, inadequate arterial oxygen content (low hemoglobin concentration or saturation), or impaired oxygen unloading from hemoglobin. These multifactorial hemodynamic abnormalities lead to ineffective tissue perfusion, in which oxygen demand exceeds oxygen delivery, which results in cellular injury. This in turn further compounds the proinflammatory and procoagulant state, precipitating multiorgan dysfunction and possibly death.

**DIAGNOSIS**

There is no specific diagnostic test for severe sepsis or septic shock. Although bacteremia has been suggested as a fundamental, pathophysiological determinant of sepsis, positive blood cultures are infrequently established during sepsis. This may be because of delays in obtaining blood cultures, prior antibiotic treatment, or inadequate culturing techniques. Because microbiological cultures are not always positive, the diagnosis of sepsis has traditionally required a known or suspected source of infection, together with two or more criteria of the systemic inflammatory response syndrome (i.e.,
fever/hypothermia, tachycardia, tachypnea, or leukocytosis/leukopenia).\textsuperscript{1} Although using the systemic inflammatory response syndrome criteria is in accord with consensus guidelines, their diagnostic performance for patients with infection is suboptimal, with a high sensitivity and low specificity.\textsuperscript{11} However, this finding is expected because of the design of the criteria, and these criteria are best used for ruling out, not ruling in, sepsis. Updated consensus criteria for the diagnosis of sepsis are currently being developed.

Early treatment is of paramount importance for severe sepsis and septic shock; hence, all diagnostic approaches should be performed simultaneously with the early administration of life-saving therapies. After a thorough history and physical examination, radiologic imaging should be done in an attempt to confirm a potential source of infection.\textsuperscript{7} Recognizing that the lung (in about 45% of cases), abdomen (about 30%), and urinary tract (about 11%) account for most infectious sites,\textsuperscript{12} microbial cultures should be sent from all suspected infectious sites and the blood as soon as possible. Cultures should be obtained before initiating antimicrobial therapy unless doing so would result in a significant (more than 45 minutes) delay in therapy.\textsuperscript{7} Only 70% of patients with septic shock have positive microbial cultures (and only 30% have positive blood cultures), which creates therapeutic challenges for clinicians. Rapid, nonculture methods of microbial detection using molecular techniques are currently being studied to aid in faster pathogen identification and recognition of antimicrobial resistance mechanisms. In addition, biomarkers (e.g., procalcitonin [PCT]) may play a role in sepsis diagnosis or in guiding antibiotic decisions.

**Box 15.1. Surviving Sepsis Campaign**

**Pharmacologic-Related Recommendations for Patients with Severe Sepsis and Septic Shock\textsuperscript{a}**

**Fluid Therapy**

1. Crystalloids as the initial fluid of choice in the resuscitation
of severe sepsis and septic shock (grade 1B)

2. Avoid the use of HES for fluid resuscitation of severe sepsis and septic shock (grade 1B).

3. Albumin in the fluid resuscitation of severe sepsis and septic shock when patients require a substantial amount of crystalloids (grade 2C)

### Vasopressors and Inotropes

1. Vasopressor therapy initially to target a MAP of 65 mm Hg (grade 1C)

2. Norepinephrine as the first-choice vasopressor (grade 1B)

3. Epinephrine when an additional agent is needed to maintain adequate pressure (grade 2B)

4. Vasopressin (AVP) 0.03 unit/minute can be added to NE with the intent of either raising MAP or decreasing NE dosage (UG). AVP doses higher than 0.03–0.04 unit/minute should be reserved for salvage therapy (failure to achieve adequate MAP with other vasopressor agents) (UG)

5. Dopamine as an alternative vasopressor agent to NE only in highly selected patients (i.e., patients with low risk of tachyarrhythmias and absolute or relative bradycardia) (grade 2C)

6. Phenylephrine is not recommended in the treatment of septic shock except when (1) NE is associated with serious arrhythmias, (2) cardiac output is known to be high and blood pressure persistently low, or (3) used as salvage therapy when combined inotrope/vasopressor drugs and low-dose AVP have failed to achieve MAP targets (grade 1C)

7. A trial of dobutamine infusion (up to 20 mcg/kg/minute) may be administered or added to vasopressor (if in use) in the presence of (1) myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output or
ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP (grade 1C)

**Antimicrobial Therapy**

1. Administration of effective intravenous antimicrobials within the first hour of recognition of septic shock (grade 1B) and severe sepsis without septic shock (grade 1C) should be the goal of therapy

2a. Initial empiric anti-infective therapy should include one or more drugs that have activity against all likely pathogens (bacterial, fungal, or both or viral) and that penetrate in adequate concentrations into the tissues presumed to be the source of sepsis (grade 1B)

2b. The antimicrobial regimen should be reassessed daily for potential de-escalation (grade 1B)

3. Low procalcitonin concentrations or similar biomarkers should be used to assist the clinician in discontinuing empiric antibiotics in patients who appear to have sepsis but have no subsequent evidence of infection (grade 2C)

4a. Combination empiric therapy for neutropenic patients with severe sepsis (grade 2B) and for patients with difficult-to-treat, multi-drug-resistant bacterial pathogens such as Acinetobacter and Pseudomonas spp. (grade 2B)

4b. Combination therapy, when used empirically in patients with severe sepsis, should not be administered for longer than 3–5 days. De-escalation to the most appropriate single-agent therapy should be done as soon as the susceptibility profile of the pathogen(s) is known (grade 2B)

5. Therapy duration should typically be 7–10 days if clinically indicated. Longer courses may be appropriate in patients who have a slow clinical response, undrivable foci of infection, bacteremia with Staphylococcus aureus, some fungal and viral infections, or immunologic deficiencies,
including neutropenia (grade 2C)

6. Antiviral therapy should be initiated as early as possible in patients with severe sepsis and septic shock of viral origin (grade 2C)

7. Antimicrobial agents should not be used in patients with severe inflammatory states determined to be of noninfectious cause (UG)

Corticosteroids

1. Not using intravenous hydrocortisone to treat adult patients with septic shock if adequate fluid resuscitation and vasopressor therapy can restore hemodynamic stability. If this is not achievable, intravenous hydrocortisone alone at a dose of 200 mg/day may be added (grade 2C)

2. Not using the ACTH stimulation test to identify those who should receive hydrocortisone (grade 2B)

Strength and evidence level of recommendations listed in parentheses are according to the Grading of Recommendations Assessment, Development and Evaluation system. The system classifies strength of recommendations as strong (1) or weak (2), and quality of evidence as high (A), moderate (B), low (C), or very low (D). Recommendations not conducive for the grading process were regarded as ungraded (UG).

ACTH = adrenocorticotropic hormone; AVP = arginine vasopressin; HES = hydroxyethyl starch; MAP = mean arterial blood pressure; NE = norepinephrine.

Procalcitonin is a precursor of calcitonin that is up-regulated by bacterial toxins and certain bacterial proinflammatory mediators such as IL-1β, IL-6, and tumor necrosis factor α, but it is neutral to cytokines that are normally released for viral infections such as
interferon-γ. As such, PCT has been studied as a diagnostic tool, a predictor of progression in sepsis stage, or a guidance tool for influencing antimicrobial decision-making. Procalcitonin concentrations rise in response to severe bacterial infections; they also correlate with sepsis-related organ failure scores and outcomes. Thus, serum PCT concentrations may help assess the severity of sepsis when combined with clinical and laboratory variables. However, although PCT may perform well in less-severe infections, it may not reliably differentiate sepsis from other noninfectious causes of systemic inflammation (pooled sensitivity 0.77, pooled specificity 0.79, area under the receiver operating characteristic curve 0.85). Thus, PCT requires further study before it can be recommended for widespread use as a diagnostic tool in sepsis. Using PCT to guide antibiotic decisions is addressed later in this chapter; other biomarkers and rapid diagnostics are discussed in detail in Chapter 13, “Laboratory Testing Considerations.”

Recognizing patients who have signs of sepsis-induced end-organ hypoperfusion (progressing to severe sepsis and septic shock) is of paramount importance. Typically, hypoperfusion is secondary to low systemic blood pressure (i.e., systolic blood pressure [SBP] less than 90 mm Hg, mean arterial pressure [MAP] less than 70 mm Hg, or an SBP decrease of more than 40 mm Hg from baseline). However, signs of organ dysfunction such as altered mental status or decreased urine output may occur in the absence of hypotension.

Serum lactate concentrations may also be used to assess for tissue hypoperfusion. In sepsis, elevations in serum lactate concentrations (greater than 4 mmol/L) are generally a result of global hypoperfusion, but other causes (e.g., impaired lactate clearance, sepsis-induced mitochondrial dysfunction, reduced pyruvate dehydrogenase activity, increased aerobic glycolysis secondary to catecholamines) must be considered and ruled out. Chapter 10, “Shock Syndromes,” contains an extensive discussion of hemodynamic values, monitoring devices, and methods to differentiate shock states. In patients with signs of sepsis-induced hypoperfusion (i.e., severe sepsis and septic shock), therapies to improve perfusion should be initiated promptly.
INITIAL AND SUBSEQUENT RESUSCITATION

The initial goals of therapy are to restore effective tissue perfusion (by administering intravenous fluids and vaso-active medications) while treating the underlying cause through antimicrobial administration and infectious source control, as applicable. Chapter 10 includes an extensive discussion of resuscitation end points and generalized treatment for shock.

**Figure 15.1** Host response in severe sepsis and septic shock.

In severe sepsis and septic shock, the host response includes both proinflammatory responses (left panel) and anti-inflammatory responses (right panel). Both pathogen and host factors contribute to the host response and contribute to the balance between pro- and anti-inflammatory response factors. The inflammatory response is commenced through detection of pathogen-associated molecular patterns (cell wall molecules expressed by pathogens) by pattern recognition receptors on the host immune cell surface (C-type lectin receptors [CLRs] and toll-like receptors [TLRs]), in the cytoplasm (nucleotide-binding oligomerization domain–like receptors [NLRs] and retinoic acid inducible gene 1–like receptors [RLRs]), or in the endosome (TLRs). Binding to these
receptors leads to the activation of NF-κB, which increases the transcription of both pro-
and anti-inflammatory cytokines. An amplified proinflammatory response leads to tissue
injury and necrotic cell death, which results in the release of damage-associated
molecular patterns that perpetuate inflammation (possibly with the same pattern
recognition receptors noted earlier). Concomitantly, the anti-inflammatory response can
lead to immunosuppression and enhanced susceptibility to secondary infections.

Patients with severe sepsis and septic shock should first be
administered a fluid challenge of crystalloid solution as quickly as
possible. Typically, the fluid challenge target is 30 mL/kg or more of
crystalloid solution.\textsuperscript{7} Although recent randomized controlled trials
simplified this requirement to the administration of 1 L of fluid challenge
over 30–60 minutes for study inclusion, the patients who were included
had on average about 30 mL/kg of intravenous fluids administered
before randomization.\textsuperscript{15,16} If blood pressure does not improve after the
fluid challenge, or if the initial serum lactate concentration is greater
than 4 mmol/L, quantitative resuscitation should be initiated. This
strategy includes using intensive diagnostics and monitoring (e.g.,
echocardiography, placing a central venous [superior vena cava]
catheter, or other mechanisms for monitoring fluid responsiveness),
setting goals for hemodynamic support, and using therapies to achieve
these goals (e.g., use and optimization of fluids, vasopressors, and
oxygen delivery methods). Priority should be placed on early,
aggressive fluid administration to optimize cardiac preload and
improvement/preservation of organ perfusion pressure.

**Early Quantitative Resuscitation**

Quantitative resuscitation originated from the landmark study of early
goal-directed therapy by Rivers and colleagues.\textsuperscript{17} This study evaluated
patients with severe sepsis and septic shock who were treated in the
emergency department for the first 6 hours after presentation. Both
study arms required insertion of central venous and arterial catheters
and had treatment goals of central venous pressure (CVP) greater than
8 mm Hg, MAP greater than 65 mm Hg, and urine output greater than
0.5 mL/kg/hour. Patients in the standard therapy group were treated at the clinician’s discretion, whereas patients in the intervention arm were uniformly treated with a protocol to achieve the resuscitation parameters, with the additional goal of central venous oxygen saturation (Scvo₂) of 70% or greater. Interventions used to increase Scvo₂ (if it was less than 70%) were packed red blood cell transfusion if the hematocrit value was 30% or below or dobutamine infusion if the hematocrit value was greater than 30%. Early, aggressive, goal-directed resuscitation was associated with a 16% absolute risk reduction in hospital mortality compared with standard therapy (30.5% vs. 46.5%, p<0.009). Several additional observational studies that included patients with early goal-directed therapy compared with historical controls have shown reduced mortality with bundle-based care.¹⁰

Despite these favorable results and support from all three iterations of the SSC guidelines, early goal-directed therapy was not universally adopted in emergency departments because of several factors. Given the design of the Rivers et al. study, it is unclear whether the use of a goal-directed protocol or the use of Scvo₂ as a treatment goal (or both) led to the study’s positive findings. In addition, the study by Rivers and colleagues received several critiques, including a higher-than-expected mortality rate in the standard therapy arm, a high absolute risk reduction in mortality (16%), the incorporation of CVP as a resuscitation goal, the non-protocolized use of antimicrobials, and its single-center nature. Furthermore, many centers faced logistical and financial barriers to implementing the protocols. As such, alternative approaches to quantitative resuscitation were developed and studied.
Figure 15.2  Mechanism of impaired tissue perfusion in severe sepsis and septic shock.

The coagulation cascade is activated in sepsis by expression of tissue factor on the vascular endothelium and on monocytes. Concomitantly, the endogenous anticoagulant pathway (tissue factor pathway inhibitor, activated protein C, and antithrombin) is impaired, and fibrinolysis is impaired (through release of plasminogen activator inhibitor type 1 [PAI-1]). As a result of an imbalance between pathways, microvascular thrombi form. Neutrophil extracellular traps (NETs) released from neutrophils further enhance thrombus generation. Microvascular thrombi and concomitant vasodilation, hypotension, and decreased red blood cell deformability further reduce tissue perfusion. Concurrently, damage to the endothelial glycocalyx layer, loss of endothelial cellular tight junctions, and impaired vascular endothelial (VE) cadherin lead to a loss of barrier function. The resultant capillary leak and interstitial edema contribute to ineffective intravascular volume, which impairs cardiac preload, stroke volume (SV), and cardiac output (CO), leading to further tissue hypoperfusion. Reprinted with permission from the Cleveland Clinic.
A large, multicenter, noninferiority study was designed to evaluate whether incorporating Scvo\textsubscript{2} as a treatment goal is a necessary component of a quantitative resuscitation protocol.\textsuperscript{18} This study randomized patients to a quantitative resuscitation protocol that incorporated Scvo\textsubscript{2} as a treatment goal or to a quantitative resuscitation protocol that was similar in all components except that it incorporated a lactate clearance of 10% or greater, instead of Scvo\textsubscript{2}, as a treatment goal. The lactate clearance strategy was determined to be noninferior to the Scvo\textsubscript{2} strategy (in-hospital mortality 17% vs. 23%, respectively; 95% confidence interval [CI] for mortality difference -3% to 15% [greater than the -10% predefined noninferiority threshold]). Of note, only 10% of the patients in each arm received a therapy specifically directed to improve either lactate clearance or Scvo\textsubscript{2}, which could have biased the study toward finding no difference between treatment arms (and incorrect rejection of a true null hypothesis of the existence of a difference between groups in this noninferiority study; a type I error). Equally relevant is that most patients in this study with septic shock (90%) achieved adequate oxygen delivery with only fluids and vasopressors.

Another multicenter, open-label study randomized ICU patients with a lactate concentration of 3 mmol/L or greater to the addition of lactate clearance of 20% or more (evaluated every 2 hours for the first 8 hours of therapy) or standard therapy (in which the treatment team was blinded for lactate concentrations).\textsuperscript{19} Both treatment arms had resuscitation targets of CVP 8–12 mm Hg, MAP 60 mm Hg or greater, and urine output greater than 0.5 mL/kg/hour. Monitoring of Scvo\textsubscript{2} was optional in the standard therapy group, but it was mandated as part of the lactate clearance group. In the lactate clearance group, if the Scvo\textsubscript{2} was 70% or greater but the lactate concentrations did not decrease by 20%, vasodilators (e.g., nitroglycerin) were initiated to improve microvascular perfusion. Adding lactate clearance as a treatment goal was not associated with a difference in hospital mortality on bivariate analysis (33.9% vs. 43.5%, p=0.067). However, after adjustment for baseline differences between groups with multivariate analysis, there was a significant difference favoring the lactate clearance group.
hazard ratio 0.61; 95% CI, 0.43–0.87; p=0.006). On the basis of these findings, in a low-level recommendation (grade 2C), the SSC has suggested targeting resuscitation to normalize lactate in patients with elevated lactate concentrations.\(^7\)

Three recently published multicenter studies further evaluated the utility of quantitative resuscitation protocols. The first study published, the Protocolized Care for Early Septic Shock (ProCESS) study, was conducted in academic medical centers in the United States. The study aimed to evaluate (1) if a quantitative resuscitation protocol was associated with improved patient outcomes compared with usual care and (2) if a quantitative resuscitation protocol was superior to usual care whether the specific protocol used by Rivers and colleagues was superior to an alternative protocol.\(^16\) The study randomized patients in the emergency department to one of three treatment arms: (1) early goal-directed therapy according to the protocol of Rivers and colleagues; (2) protocol-based standard care that did not require the use of a central venous catheter but that used clinician judgment for fluid administration and hypoperfusion, together with a shock index (heart rate/SBP) less than 0.8 and an SBP greater than 100 mm Hg as resuscitation targets; or (3) usual care (treatment according to the bedside physician). There was no difference in 60-day mortality between the treatment arms (early goal-directed therapy 21.0% vs. protocol-based standard care 18.2% vs. usual care 18.9%, p=0.83 for a comparison of the two protocol-based groups combined and the usual care group, p=0.55, for the three-group comparison).

The second published evaluation, the Australasian Resuscitation in Sepsis Evaluation (ARISE) study, also enrolled patients presenting to the emergency department with severe sepsis or septic shock.\(^15\) The study was conducted in both academic and nonacademic centers mainly in Australia and New Zealand, and patients were randomized to early goal-directed therapy (with a protocol very similar to the one used by Rivers and colleagues) or usual care. Patients had to have been initiated on antimicrobials before study entry (eliminating a potential confounder from the study by Rivers and colleagues). There was no difference in 90-day mortality between the treatment arms.
(early goal-directed therapy 18.6% vs. usual care 18.8%, p=0.90). In addition, there was no difference between treatment arms in prespecified subgroup analyses or mortality rates at different time points (including hospital mortality). Because the enrolled patients had lower severity-of-illness scores and lower mortality at 90 days, it could be suggested that the patients enrolled in this study were less acutely ill than the patients enrolled in the U.S. early goal-directed therapy study. However, about 70% of the patients in the Australasian study had septic shock at randomization (only 54% of patients in the U.S. trial met this criterion), suggesting that the patients were critically ill and the intended population was studied.

The third study, the ProMISE (Protocolised Management in Sepsis) trial, was conducted by the UK Intensive Care National Audit & Research Centre and used a research design identical to that of the ARISE study to evaluate the utility of goal-directed resuscitation.\textsuperscript{20} The study enrolled 1,260 patients randomized equally to either early goal-directed therapy or usual care. Similar to the previous studies, no difference in 90-day mortality was seen between those treated with early goal-directed therapy and those treated with usual care (29.5% vs. 29.2%, p=0.90). The mortality rate in this study was in range with the mortality rates from the ARISE and ProCESS studies, all of which were notably lower than in the initial study by Rivers and colleagues. These consistent findings of lower mortality rates in the contemporary studies suggests that care of patients with septic shock has evolved since the Rivers et al. study and that, with ubiquitous early recognition and aggressive resuscitation, protocolized care may no longer be mandatory. Indeed, the progression of care and resultant improvement in outcomes for patients with severe sepsis and septic shock during the past 10–15 years has been remarkable.\textsuperscript{21}

The recently published quantitative resuscitation studies highlight the benefits of timely administration of antibiotics and intravenous fluids, which should be a focus of the early care of patients with severe sepsis and septic shock. Quantitative resuscitation efforts and use of monitoring devices should be individualized for patients on the basis of assessments of blood pressure, adequate end-organ perfusion, lack of
fluid responsiveness, and adequate oxygen delivery; these components are reviewed in detail in the Shock Syndromes chapter. After an initial fluid challenge, fluid therapy should be continued as long as the patient continues to be fluid responsive. Vasopressors should be applied to initially target a MAP of 65–70 mm Hg, but the MAP goal may subsequently be adjusted if adequate organ perfusion is not attained (particularly in patients with chronic hypertension). Adequate tissue oxygen delivery should be ensured, likely through a combination of lactate clearance and an $\text{Scvo}_2$ of 70% or greater as treatment goals.

**Other Resuscitation Goals**

As discussed in Chapter 10, MAP is the true driving pressure for peripheral blood flow (and end-organ perfusion) and is preferred to SBP as a therapeutic target. A multi-center open-label study randomized patients with septic shock to resuscitation with a MAP goal of either 65–70 mm Hg (low-target group) or 80–85 mm Hg (high-target group). The higher MAP target was achieved through vasopressor administration; patients in the high-target group had a significantly higher infusion rate and longer duration of vasopressors than did patients in the low-target group, but there was no difference between groups in total volume of fluid administration. Nor was there any difference between treatment arms in 28-day mortality (34.0% in the low-target group vs. 36.6% in the high-target group, $p=0.57$). However, the incidence of atrial fibrillation was significantly higher in the high-target group (6.7% vs. 2.8%, $p=0.02$). In an a priori–defined subgroup analysis of patients with chronic hypertension (with randomization stratified according to this covariate), those randomized to the high-target group had a lower incidence of a doubling of the serum creatinine concentration (38.9% vs. 52.0%, $p=0.02$, stratum interaction $p=0.009$) and less need for renal replacement therapy (31.7% vs. 42.2%, $p=0.046$, stratum interaction $p=0.04$). Analyses of these data suggest that an initial MAP goal of 65–70 mm Hg (as suggested in the SSC guidelines) should be used, but the MAP goal may need to be adjusted if the patient has persistent signs of
Transfusions of packed red blood cells are often given to patients with shock and evidence of hypoperfusion to increase oxygen delivery. This practice was incorporated into the early goal-directed therapy algorithm from Rivers and colleagues noted earlier (if the hematocrit value was less than 30%) and was previously endorsed by the SSC guidelines. A multicenter study compared two different transfusion thresholds in patients with septic shock. The study enrolled patients with septic shock and a hemoglobin concentration below 9 g/dL to receive a packed red blood cell transfusion if their hemoglobin concentration was 7 g/dL or less (lower threshold) or 9 g/dL or less during their ICU stay. As expected, patients allocated to the lower-threshold group less commonly received a packed red blood cell transfusion and had lower hemoglobin concentrations. There was no difference between treatment arms in 90-day mortality (43.0% in the lower-threshold group vs. 36.6% in the higher-threshold group, p=0.44). Patients in the lower-threshold group did not have a higher incidence of ischemic events in the ICU (7.2% vs. 8.0%, p=0.64), and there was no difference in outcomes between groups in the subgroup of patients with chronic cardiovascular disease (relative risk [RR] 1.08 [95% CI, 0.75–1.40], p=0.25 for heterogeneity of treatment effect by subgroup; only 14% of the overall population had chronic cardiovascular disease). Although the study did not specifically evaluate the practice of transfusing blood in patients with evidence of hypoperfusion (low Scvo2 or elevated lactate concentrations) associated with a low hemoglobin concentration, the median Scvo2 at baseline was less than 70%, and lactate concentrations were greater than 2 mmol/L in both groups, suggesting that most patients had evidence of hypoperfusion. Evaluations of these data suggest that using a hemoglobin transfusion threshold of 7 g/dL or lower is safe for most patients, including those with severe sepsis and septic shock.

Resuscitation targeted to improving microcirculatory perfusion is a potential new therapeutic frontier. Studies have shown the following: microcirculation is often altered in patients with sepsis, persistent microvascular alterations are associated with multisystem organ failure
and death, alterations are more severe in non-survivors than in survivors, and improvements in microcirculatory blood flow correspond with improved patient outcomes.\textsuperscript{25} Impaired microcirculatory perfusion may at least partly explain why patients have elevated lactate concentrations despite achieving (macrovascular) hemodynamic goals.

Several strategies to improve microcirculatory perfusion have been investigated with mixed results. In a nonrandomized trial, fluid resuscitation improved microvascular perfusion in early, but not late, sepsis.\textsuperscript{26} Another study found that microcirculatory perfusion improved with passive leg raising or fluid administration in patients who were fluid responsive.\textsuperscript{27} Using vasopressors to increase MAP and tissue perfusion is theoretically attractive, but using norepinephrine to increase MAP to greater than 65 mm Hg has not been associated with correction of impaired microcirculatory perfusion.\textsuperscript{28-30} Likewise, vasodilators may induce capillary vasodilation and improve blood flow, but in a randomized trial of patients who underwent quantitative resuscitation, adding nitroglycerin was not associated with improved microcirculatory blood flow. In-hospital mortality was numerically higher in patients allocated to nitroglycerin than in placebo, but this difference was not statistically significant (34.3\% vs. 14.2\%, $p=0.09$).\textsuperscript{31} In addition, initiating inhaled nitric oxide after quantitative resuscitation did not improve microcirculatory flow or lactate clearance.\textsuperscript{32} As such, neither vasopressors nor vasodilators can currently be recommended solely for improving microcirculatory blood flow. Finally, the effects of inodilators (e.g., dobutamine) and a pure inotrope (levosimendan) on microcirculatory blood flow have been studied. A prospective open-label study evaluated the effects of dobutamine 5 mcg/kg/minute initiated after quantitative resuscitation (but within the first 48 hours of presentation). Dobutamine significantly improved microcirculatory perfusion compared with baseline.\textsuperscript{33} In a small study, levosimendan improved microcirculatory blood flow more effectively than did dobutamine,\textsuperscript{34} but levosimendan is not available for use in the United States. Of interest, the beneficial effects of dobutamine and levosimendan in these studies were unrelated to changes in cardiac index or blood pressure, suggesting a mechanism of benefit separate
from (or in addition to) the inotropic effects of the agents. In summary, fluid resuscitation and the initiation of dobutamine appear to improve microcirculatory perfusion, but widespread use of these agents solely to improve microcirculatory blood flow cannot be recommended at this time.\textsuperscript{25} Currently, it is still unknown whether using these therapies to improve microcirculatory perfusion can improve patient outcomes such as mortality.

**Severe Sepsis and Septic Shock Management Bundle**

The SSC guidelines include a core set of initial process steps and treatment goals grouped into a care bundle for the treatment of patients with severe sepsis and septic shock. These bundles were developed as a quality improvement program, in conjunction with the Institute for Healthcare Improvement, with a goal of reducing patient mortality by integrating the recommendations from the SSC guidelines into bedside care. Previous versions of the SSC guidelines included both a resuscitation bundle and a management bundle to be completed within the first 6 hours and 24 hours of presentation, respectively.

As part of a performance improvement initiative (SSC phase III), hospitals were invited to contribute data regarding bundle compliance and patient outcomes in exchange for educational materials and feedback regarding performance. An analysis of more than 15,000 patients from 165 hospitals in Europe, South America, and the United States showed that compliance with both the resuscitation bundle and the management bundle increased linearly each quarter during a 2-year period.\textsuperscript{6} Although compliance improved over time, fulfillment of every bundle element at the end of the 2-year observation period was relatively low (31.3\% for the resuscitation bundle and 36.1\% for the management bundle). During the same observation period, unadjusted hospital mortality decreased from 37\% to 30.8\% (p=0.001). On multivariate analysis, each quarter that a site participated in the initiative was independently associated with a 3\% decrease in hospital mortality (odds ratio [OR] 0.97; 95\% CI, 0.96–0.99; p=0.0006). Although a cause-and-effect relationship cannot be established from
these data, the association between bundle implementation and decreased mortality suggests that using a care bundle is an effective way to improve the care of patients.

After further analysis of data from SSC phase III, the management bundle was removed, and the resuscitation bundle was broken into two parts (items to be completed within 3 and 6 hours) as a care bundle in the 2012 SSC guidelines. In 2015, in response to the new evidence from the three previously noted quantitative resuscitation studies, the SSC Executive Committee released an update to the SSC bundles. The update acknowledges the findings of the three studies and amends the bundles to use techniques in addition to CVP and Scvo\textsubscript{2} to reassess fluid responsiveness and tissue perfusion. These techniques include either use of a repeat focused examination by a licensed practitioner to evaluate for vital signs, cardiopulmonary findings, capillary refill, heart rate, and skin findings or use of at least two of the following: CVP, Scvo\textsubscript{2}, bedside ultrasonography, or dynamic markers of fluid responsiveness.

A severe sepsis and septic shock care bundle was adopted by the National Quality Forum (NQF) with a goal of improving early recognition and treatment of patients with severe sepsis and septic shock. Of note, the care bundle from the NQF differs from that published in the 2012 SSC guidelines but is very similar to the updated SSC bundle (Box 15.2). The care bundle from the NQF has been adopted by the Centers for Medicare & Medicaid Services as a chart-abstracted quality measure, with reimbursement to be influenced beginning in 2017.

The adjustment of the SSC bundle and the implementation of sepsis as a quality measure will likely lead to a shift in resuscitation approaches for many clinicians. To prepare for and implement this new quality measure, practitioners should systematically evaluate their institutional compliance and implement broad process steps to ensure compliance. These steps may include, but are not limited to, patient identification by clinical decision support tools in the electronic medical record and implementation of care paths and order sets for treatment. The SSC has distributed a guidance document for implementing the
2012 SSC guidelines, which may serve as a valuable resource for initiating and optimizing quality initiatives related to the new quality measure.38

**Continued Care Beyond Initial Resuscitation**

Uncertainty persists regarding resuscitation end points and hemodynamic targets after the first 6 hours of patient presentation. Therapy should be directed toward maintaining adequate end-organ perfusion and normalization of lactate concentrations, but the specific methods to achieve these goals should be patient-specific. A strategy of systematically increasing cardiac output to predefined “supranormal” levels was not associated with a mortality benefit; hence, it is not recommended.39

The liberal use of fluid boluses during the early stages of resuscitation should be undertaken with caution beyond the initial hours to avoid giving excessive fluids. In a retrospective analysis of data from a randomized controlled trial of patients with septic shock, patients in the highest quartile of fluid balance had a significantly higher mortality rate than did patients in the lowest two quartiles. This association was present when fluid balance was evaluated at both 12 hours and 4 days after study enrollment. In the same analysis, a CVP greater than 12 mm Hg conferred a higher risk of mortality than did a lower CVP.40 Fluid administration can be limited by only giving fluid in patients who are proved or predicted to respond to fluid. This is best accomplished using dynamic markers of fluid responsiveness, as discussed in Chapter 10.

**ANTIMICROBIALS**

Because infection is the underlying cause of septic shock, antimicrobial therapy should be initiated at the same time as initial resuscitation efforts. The SSC guidelines recommend that adequate empiric antibiotics be initiated within 1 hour after recognition of severe sepsis or septic shock.7 This recommendation is informed by a multicenter,
retrospective study of patients with septic shock, which found that within the first 6 hours from the onset of hypotension, each hour of delay in the administration of appropriate antibiotics was associated with a 7.6% decrease in hospital survival.\textsuperscript{41} Other studies have further shown the importance of empiric antimicrobials used in conjunction with a quantitative resuscitation protocol, associating the administration of antimicrobials either before shock or within the initial hour of shock with improved survival.\textsuperscript{42,43} Source control measures (e.g., drainage of an abscess, debridement of infected necrotic tissue, or removal of a potentially infected device [including intravascular access devices]), as applicable, should also be undertaken as soon as possible (within 12 hours after the diagnosis is made).

Initial empiric therapy should include one or more drugs with activity against all likely pathogens. The most commonly isolated pathogens in critically ill patients are gram-negative bacteria (62%), gram-positive bacteria (47%), and fungi (19%)\textsuperscript{44}; a careful analysis of an individual patient’s risk factors for each pathogen should be undertaken, with the appropriate therapy administered. In an observational study of more than 5,700 patients with septic shock, patients who received initial appropriate antimicrobials had a significantly higher hospital survival rate than did those who received initial inappropriate antimicrobials (52.0% vs. 10.3%, p<0.0001).\textsuperscript{45}

**Box 15.2. Severe Sepsis and Septic Shock Management Bundle\textsuperscript{a}**

**Accomplished within 3 hours of presentation\textsuperscript{b}**

A. Measure lactate concentration

B. Obtain blood cultures before administering antibiotics

C. Administer broad-spectrum antibiotics

If septic shock is present,\textsuperscript{c} additional measures to be accomplished within 6 hours of presentation\textsuperscript{b}
D. Administer crystalloid 30 mL/kg for hypotension or lactate ≥ 4 mmol/L\textsuperscript{d}

E. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation to maintain a mean arterial blood pressure ≥ 65 mm Hg)

F. If persistent arterial hypotension after initial fluid administration (mean arterial blood pressure < 65 mm Hg) or if initial was lactate ≥ 4 mmol/L, reassess volume status and tissue perfusion, and document findings\textsuperscript{e}

G. Remeasure lactate if the initial lactate concentration was elevated\textsuperscript{f}

\textsuperscript{a}Applies to all patients presenting with severe sepsis and septic shock. Patients are excluded from the measure if they have advanced directives for comfort care, if they have clinical conditions that preclude total measure completion (i.e., mortality within the first 6 hours of presentation), if a central line is clinically contraindicated, if a central line was tried but could not be successfully inserted, if a patient or surrogate decision-maker declined or is unwilling to consent to such therapies or central line placement, or if a patient was transferred to an acute care facility from another acute care facility.

\textsuperscript{b}Time of presentation is defined as the time of triage in the emergency department or, if the patient is located in another care venue, from the earliest chart annotation consistent with all elements of severe sepsis or septic shock ascertained through chart review.

\textsuperscript{c}Septic shock defined as either hypotension (to systolic blood pressure [SBP] less than 90 mm Hg, mean arterial blood pressure less than 70 mm Hg, or an SBP decrease greater than 40 mm Hg for known baseline) or a lactate concentration of 4 mmol/L or greater.

\textsuperscript{d}In the Centers for Medicare & Medicaid Services quality measure, crystalloid 30 mL/kg must be administered within 3 hours of presentation if septic shock is present.

\textsuperscript{e}To meet the requirements, one of the following must be documented: (1) a focused examination by a licensed independent practitioner, including vital signs, cardiopulmonary, capillary refill, heart rate, and skin findings, or (2) any two of the following: measure central venous pressure, measure central venous oxygen saturation, perform bedside cardiovascular ultrasonography, or perform dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge.
Using combination antibacterial therapy (at least two different classes of antibiotics) increases the likelihood that at least one drug will be effective against the pathogen, particularly in the setting of known or suspected multi-drug-resistant organisms such as Pseudomonas aeruginosa. Combination therapy is likely indicated for patients who are severely ill with a high baseline chance of mortality, perhaps restricted to those with septic shock. A randomized controlled trial of patients with severe sepsis that allocated patients to meropenem monotherapy or combination therapy with meropenem and moxifloxacin did not detect a difference between groups in mean Sequential Organ Failure Assessment scores over 14 days (7.9 points vs. 8.3 points, p=0.36) or in mortality rates at 28 days or 90 days.46 Important caveats to this study are that the patient population studied was at a low risk of resistant pathogens (half of the patients had community-acquired infection) and that moxifloxacin does not adequately cover pathogens with a high likelihood for multidrug resistance (e.g., P. aeruginosa and Acinetobacter spp.). A meta-analysis that included 50 studies and more than 8,500 patients with sepsis did not detect an overall mortality benefit of combination antibacterial therapy compared with monotherapy (pooled OR of death 0.86; 95% CI, 0.71–1.03, p=0.09); however, a stratified analysis showed significantly lower mortality with combination therapy in more severely ill patients (mono-therapy risk of death greater than 25%, pooled OR of death with combination therapy 0.54; 95% CI, 0.45–0.66, p<0.001). The benefit of combination therapy was confined to patients with septic shock (with no benefit of combination therapy in patients without shock). In addition, a meta-regression analysis, which tried to elucidate the differences in the

\[\text{In the Centers for Medicare & Medicaid Services quality measure, this is defined as a lactate concentration } \geq 2 \text{ mmol/L.}\]

benefit seen with combination therapy on the basis of baseline mortality risk, showed a significant benefit of combination therapy with a mortality risk greater than 25%.\textsuperscript{47} Analyses of these data suggest that severely ill patients will likely benefit from combination antibacterial therapy. Empiric combination therapy is recommended for a maximum of 3–5 days\textsuperscript{7}; the use of combination therapy for definitive treatment is beyond the scope of this chapter.

As noted in Chapter 12, severe sepsis and septic shock can significantly affect the probability of attaining the antimicrobial PK/PD target. Most notably, the volume of distribution of hydrophilic antibiotics (e.g., β-lactams, amino-glycosides, and vancomycin) will be increased. Clearance may either be increased (in the setting of augmented renal clearance) or decreased (in the presence of end-organ dysfunction).\textsuperscript{48} A PK/PD study of the first dose of β-lactams in patients with severe sepsis and septic shock suggested that the PK/PD target was attained in less than 50\% of the patients given ceftazidime 2 g (28\% target attainment), cefepime 2 g (16\%), and piperacillin/tazobactam 4 g/0.5 g (44\%). The PK/PD target was attained in 75\% of patients receiving meropenem 1 g. For each antibiotic, the volume of distribution was higher and the clearance was lower than in healthy volunteers.\textsuperscript{49}

Similarly, a multicenter cross-sectional study of β-lactam concentrations in critically ill patients found that the minimum PK/PD target of at least 50\% of free drug time above the minimum inhibitory concentration (MIC) ($50\% \text{fT}>\text{MIC}$) was not achieved in 16\% of patients with an infection. Of importance, achievement of $50\% \text{fT}>\text{MIC}$ or $100\% \text{fT}>\text{MIC}$ was independently associated with a higher likelihood of a positive outcome on multivariable analysis (OR 1.02; 95\% CI, 1.01–1.04 and OR 1.56; 95\% CI, 1.15–2.13, respectively).\textsuperscript{50} Analyses of these data suggest that a loading dose approach for these antibiotics in patients with severe sepsis and septic shock is likely necessary. In addition, the impact of methods to improve the fT>MIC should be studied further.

Antimicrobial therapy should be evaluated on a daily basis to determine whether opportunities for de-escalation or discontinuation exist. Continued use of broad-spectrum antimicrobial therapy may
cause untoward adverse effects and promote the development of resistant pathogens. Whether to use de-escalation may be a clear-cut decision in infections in which a contributive pathogen has been identified; in such cases, antimicrobial therapy should be reduced to the narrowest-spectrum agent with adequate activity. However, de-escalation may be more challenging in patients with culture-negative sepsis, where clinical judgment, baseline suggestion of infection, local pathogen epidemiology, and likely source will dictate further changes in antimicrobials. For patients with proven or high suggestion of infection, antimicrobials are typically continued for 7–10 days, although longer courses may be indicated in patients with a poor clinical response, those with bacteremia, and those who are immunocompromised.

Procalcitonin has been studied as a tool to assist with clinical decisions regarding antibiotic use and duration, and its use was endorsed as a low-level (grade 2C) recommendation by the 2012 SSC guidelines. The assay and corresponding algorithms have been evaluated for antibiotic initiation, antibiotic cessation, and the combination of both strategies. These strategies assume PCT availability from an institutional laboratory. If the PCT turnaround time is more than 24 hours, the effects of minimizing antimicrobial treatment days may be limited. According to current evidence, PCT should not routinely be measured in patients without signs and symptoms of infection. The decision to initiate patients on antibiotics without signs and symptoms of infection using PCT alone would probably lead to antimicrobial overuse and possible adverse effects associated with antimicrobial therapy. In the largest PCT study of critically ill patients to date, 1,200 patients were randomized to either a PCT alert strategy or standard of care. For those randomized to intervention, a PCT concentration greater than 1.0 mcg/L generated an alert that mandated clinical intervention, which included use of microbiological cultures, additional radiologic assessment, and initiation or expansion of antimicrobial coverage. Overall, this strategy did not lead to an improvement in mortality or time to appropriate antibiotics. However, patients had a greater need for mechanical ventilation, a prolonged ICU length of stay, and prolonged antibiotic use.
In critically ill patients with signs and symptoms of infection, including those with severe sepsis and septic shock, a baseline PCT (at the time of the symptoms) should not be used to determine whether antibiotics should be initiated. Withholding antimicrobials in patients with severe sepsis and septic shock and a low PCT concentration may have severe negative consequences. In addition, the compliance rate for withholding antibiotics for a low PCT in this scenario has consistently been low in randomized studies. The compliance rate in clinical practice is likely even lower than that in clinical studies; however, this has not been evaluated. If a baseline PCT is obtained, it should only be used to trend the PCT concentration for possible early discontinuation of antibiotics. In a study of patients with signs and symptoms of infections to determine whether a PCT-guided strategy would limit the initiation of antibiotics, no difference in antibiotic use was seen.\textsuperscript{52} However, this finding was likely confounded by a 36% clinician compliance rate with the recommendation to withhold antimicrobials when the PCT was low. This is in sharp contrast to the 86% compliance rate with the recommendation to initiate antibiotics when the PCT was high.

It may be helpful to obtain a baseline PCT for trending purposes in critically ill patients with signs and symptoms of infection. A low PCT (or a substantial decrease from baseline) during antibiotic treatment should be used to shorten the duration of antimicrobial therapy.\textsuperscript{7} This can be accomplished by either eliminating unnecessary antibiotics in patients without signs and symptoms of infection or shortening the course of therapy for patients with an infection. Several studies have evaluated the utility of a PCT-guided strategy for determining the appropriate time to discontinue or de-escalate antibiotics.\textsuperscript{53-60} These studies consistently show that PCT guidance for discontinuing antimicrobial therapy led to decreases in antibiotic use without an untoward outcome effect.\textsuperscript{61} This has also been shown in various ICU patient populations with differing severity of illness, including patients with severe sepsis and septic shock. Ideally, if a PCT algorithm is implemented, it should be combined with formalized antimicrobial stewardship efforts. In fact, when a PCT algorithm was combined with twice-weekly infectious stewardship rounds in a randomized trial aimed
at limiting the duration of antibiotics, compliance with PCT algorithm recommendations was greater than 97%.\textsuperscript{58} Many different PCT guidance algorithms exist; Figure 15.3 represents a reasonable approach to using PCT for antibiotic cessation.

---

**AGENTS USED TO TREAT SHOCK**

**Fluid Therapy**

**Crystalloids**

Resuscitation fluids are commonly given for patients in the ICU, with 37% of patients receiving this therapy in a 24-hour period in a cross-sectional study.\textsuperscript{62} Crystalloids (i.e., 0.9% sodium chloride or lactated Ringer solution) are the initial fluid type of choice,\textsuperscript{7} particularly for an initial fluid challenge. The Saline versus Albumin Fluid Evaluation (SAFE) study compared 0.9% sodium chloride with 4% albumin in a heterogeneous ICU population of almost 7,000 patients. Overall, the study did not detect a difference in 28-day mortality between groups (20.9\% vs. 21.1\%, \textit{p}=0.87).\textsuperscript{63} Of note, however, this was not a study of strictly initial fluid resuscitation because the allocated study fluid was used for all fluid resuscitation in the ICU until death, discharge, or 28 days after randomization. Despite some limitations, evaluations of these data have informed the SSC recommendation of crystalloids as the initial fluid type, particularly given their low cost.

Crystalloid solutions with relatively low chloride content (“chloride-poor” or “balanced salt” solutions) are an attractive alternative to 0.9% sodium chloride (see Chapter 10 for further discussion). Administration of chloride-rich fluids may lead to afferent renal arteriole vasoconstriction (leading to a decrease in renal perfusion and kidney injury) and may cause a metabolic acidosis by lowering the strong ion difference. As such, crystalloids that better approximate the electrolyte composition of plasma (e.g., lactated Ringer solution) have been evaluated. A propensity-matched retrospective cohort study of medical ICU patients with sepsis found that receipt of a balanced solution
compared with 0.9% sodium chloride was associated with a lower incidence of in-hospital mortality (19.6% vs. 22.8%, p=0.001). Unlike in analyses of general critical care patients, this study did not detect a difference in the incidence of acute renal failure between groups, which leads to questions regarding the mechanism of the detected mortality difference between groups.\textsuperscript{64} In addition, a recently published systematic review and network meta-analysis of patients with sepsis suggested a lower mortality rate in patients resuscitated with balanced solutions than in patients resuscitated with 0.9% sodium chloride (OR 0.78, credibility interval 0.58–1.05; low confidence in estimate of effect).\textsuperscript{65} Balanced salt solutions are not without adverse effects; they may lead to hyponatremia and hypotonicity (with lactated Ringer solution) or cardiotoxicity (with acetate-containing solutions) when administered in large volumes. Although intriguing, analyses of these data do not definitively support the benefit of balanced salt solutions, and a large randomized trial comparing these crystal-loid solutions is eagerly awaited.
Figure 15.3 An approach to procalcitonin use for antibiotic cessation.

ABX = antibiotics; PCT = procalcitonin.

Colloids

Albumin for Resuscitation

Iso-oncotic (4%–5%) albumin may be used as a component of the fluid resuscitation strategy. Despite decades of research, though, the choice between crystalloids and albumin for fluid resuscitation in patients with severe sepsis and septic shock remains controversial. A prospectively
defined subgroup analysis of the SAFE study evaluated the effect of albumin 4% compared with that of 0.9% sodium chloride in patients with severe sepsis and septic shock. The unadjusted RR of death with albumin was 0.87 (95% CI, 0.74–1.02) in patients with severe sepsis and 1.05 (95% CI, 0.94–1.17) in patients without severe sepsis (p=0.06 for heterogeneity of treatment effect by subgroup). In a multivariate analysis that accounted for baseline factors, albumin was associated with a lower mortality risk (OR 0.71; 95% CI, 0.52–0.97; p=0.03). A systematic review and fixed-effect meta-analysis of albumin compared with alternative fluids for resuscitation in patients with sepsis found an association between albumin use and lower mortality (OR 0.82; 95% CI, 0.67–1.0; p=0.047). The benefit of albumin was retained when the analysis was restricted to crystalloids as the comparator (OR 0.78; 95% CI, 0.62–0.99; p=0.04). These data should be interpreted with caution, however, because many of the included studies had poor methodological quality, and when a random-effects model was used, the results for the overall analysis were not statistically significant (OR 0.84; 95% CI, 0.69–1.02, p=0.08). These data have renewed interest in 4%–5% albumin as a resuscitation fluid for patients with severe sepsis and septic shock. Indeed, the 2012 SSC guidelines suggest albumin as a component of the fluid resuscitation regimen when patients require a substantial amount of crystalloids.

Many clinicians find this recommendation from the SSC challenging to implement into practice because there is no clear definition of a “substantial amount” of crystalloids, and the recommendation is weak with low-quality evidence (grade 2C). Proponents of crystalloids note the predominant use of crystalloids in quantitative resuscitation studies, the patient enrollment after initial resuscitation in most studies in the previously noted meta-analysis, the lack of a prospective study favoring albumin that enrolled only patients with severe sepsis, and the high cost of albumin. Advocates for albumin note its more efficacious plasma volume expansion, its non-fluid (e.g., ligand binding and antioxidant) properties, and the subgroup and meta-analysis findings noted earlier. Until further data are available, it seems reasonable to
use crystalloids preferentially to iso-oncotic albumin for initial fluid resuscitation, particularly for the initial fluid challenge.

If a component of a patient’s fluid resuscitation strategy includes colloids, it may be challenging to calculate the total amount of “crystalloid-equivalent” fluid a patient has received. This is particularly important when colloids are used as a component of initial resuscitation and at least 30 mL/kg of crystalloid must be administered. Approximate intravenous fluid equivalencies for crystalloids and colloids are included in Table 15.2 to assist with this calculation.67

**Hydroxyethyl Starch for Resuscitation**

Synthetic colloids such as hydroxyethyl starch (HES) have been suggested as an alternative therapy for fluid resuscitation. Two large studies comparing resuscitation with HES to resuscitation with crystalloids in patients having severe sepsis and septic shock have been completed with similar findings (studies evaluating HES in nonselected critically ill patients are discussed in Chapter 10). In the first study, patients with severe sepsis who were allocated to pentastarch (a HES formulation) had a significantly higher incidence of acute renal failure (34.9% vs. 22.8%, p=0.002) and a greater need for renal replacement therapy (31.0% vs. 18.8%, p=0.001) than did patients with severe sepsis allocated to lactated Ringer solution, with no difference in 28-day mortality (26.7% vs. 24.1%, p=0.48).68 In a more recent study, patients with severe sepsis randomized to receive HES had a significantly higher 90-day mortality (51% vs. 43%, p=0.03) and need for renal replacement therapy (22% vs. 16%, p=0.04) than did patients with severe sepsis randomized to receive Ringer acetate solution.69 The findings in this study did not appear to depend on the time duration between ICU admission and study enrollment, surgery, type of fluid given before randomization, or markers of shock severity in a post hoc subgroup analysis.70 A systematic review and meta-analysis of tetrastarch (a HES formulation) in patients with severe sepsis found an association between HES use and 90-day mortality (RR 1.13; 95% CI, 1.02–1.25; p=0.02), renal replacement therapy (RR 1.42; 95% CI, 1.09–1.85; p=0.01), and blood product transfusion (RR
The increased mortality and increased need for renal replacement therapy led to a strong recommendation against the use of HES for fluid resuscitation in patients with severe sepsis and septic shock in the 2012 SSC guidelines. 

**Albumin Replacement**

Hyperoncotic (20%–25%) albumin replacement may be beneficial in patients with septic shock. An open-label study compared albumin replacement (with 20% albumin) with a goal serum albumin concentration of 3 g/dL plus crystalloid solution administration with crystalloid solution administration alone in patients with severe sepsis or septic shock. There was no difference between the albumin and crystalloid groups in the incidence of 28-day mortality (31.8% vs. 32.0%, p=0.94), but patients allocated to albumin had a shorter time to cessation of vasoactive agents (median 3 days vs. 4 days, p=0.007). A post hoc subgroup analysis of patients with septic shock at enrollment showed that those randomized to albumin had a lower 90-day mortality rate (RR 0.87; 95% CI, 0.77–0.99); there was no difference in 90-day mortality in patients without septic shock (RR 1.13; 95% CI, 0.92–1.39; p=0.03 for heterogeneity). Of note, in multivariable analysis, depending on which variables were entered into the model, the significant difference in 90-day mortality was no longer seen. Analyses of these data suggest that albumin replacement does not improve outcomes in patients with severe sepsis but that albumin replacement may have hemodynamic (and potentially mortality) advantages in patients with septic shock. Hence, the role of albumin replacement in patients with septic shock warrants further study.

**Vasoactive Agents and Inotropes**

**Catecholamine Vasopressors**

Vasoactive agents should be initiated in patients who have signs of end-organ hypoperfusion despite fluid resuscitation, with the goal of attaining an initial MAP of 65 mm Hg. Selecting the most appropriate drug depends on the goal of therapy: either to increase systemic vascular resistance (for which vasopressors are used) or to improve
cardiac output (for which inotropes are used). Norepinephrine and dopamine have traditionally been the goto vasopressors for patients with septic shock, although no strong data existed to guide selection between the two. However, a large, randomized trial compared blinded norepinephrine and dopamine administration in patients with shock (62% had septic shock). Overall, there was no significant difference in 28-day mortality between the norepinephrine and dopamine groups (48.5% vs. 52.5%, p=0.10). Of importance, however, patients randomized to norepinephrine had significantly fewer days on vasopressors and a lower incidence of arrhythmias (12.4% vs. 24.1%, p<0.001).\(^5\) In addition, a meta-analysis of randomized trials that compared norepinephrine with dopamine for the treatment of patients with septic shock found a higher risk of short-term mortality (RR 1.12; 95% CI, 1.01–1.20; p=0.035) and arrhythmias (RR 2.34; 95% CI, 1.46–3.77; p=0.001) in patients allocated to dopamine.\(^73\) In light of these data, the SSC strongly recommends norepinephrine as the first-choice vasopressor in patients with septic shock.

The optimal approach to using vasoactive agents and inotropes beyond the choice of initial vasopressor is unclear, but the choice should be based on patient-specific clinical factors. Potential interventions could include the use of norepinephrine monotherapy (with appropriate dose escalation) or the initiation of an additional therapy (i.e., a second catecholamine vasopressor, arginine vasopressin, corticosteroids, an inotrope, or a combination of these therapies). The optimal time or norepinephrine dose at which to consider additional therapies is unknown. Moreover, a dose that constitutes the failure of norepinephrine is not well defined in the literature, and the maximal doses used by clinicians (or institutions) are variable and often subjective.

The SSC guidelines recommend epinephrine (added to or potentially substituted for norepinephrine) when a vasoactive agent is needed in addition to norepinephrine. Although epinephrine is not commonly used in the United States, its use in Europe and other parts of the world is more common because of its relatively low cost. Two large studies have compared the effects of epinephrine with those of norepinephrine
in patients with shock. In the first study, patients with septic shock were randomized to norepinephrine with or without dobutamine or epinephrine. There was no difference between groups in 28-day mortality (40% vs. 34%, p=0.31), but patients allocated to epinephrine had significantly higher lactate concentrations on day 1 (p=0.003) and lower arterial pH values on each of the first 4 study days.\textsuperscript{74} Caution should be used in concluding that a difference in mortality between epinephrine and norepinephrine does not exist because the study was powered to detect a 20% absolute difference in mortality rates, and a smaller difference between agents cannot be ruled out. In a second study of patients with mixed shock types (55% had septic shock) randomized to norepinephrine or epinephrine, there was no difference between agents in the time to achievement of a goal MAP (median 40 hours vs. 35.1 hours, p=0.26) or in the median number of vasopressor-free days at day 28 (25.4 days vs. 26.0 days, p=0.31). Patients allocated to epinephrine, though, had higher heart rates and lactic acid concentrations on the first study day (but not on subsequent days) and were more often withdrawn from the study by the treating clinician (12.9% vs. 2.8%, p=0.002).\textsuperscript{75} Analyses of these data suggest that epinephrine offers no efficacy benefits over norepinephrine and that epinephrine is associated with an increased incidence of adverse effects (at least initially).

The benefit of adding epinephrine to norepinephrine (whether this approach has a norepinephrine-sparing effect or whether it is best used in norepinephrine failure) is unclear. Although norepinephrine may cause tachycardia or tachyarrhythmias (often the impetus to limit doses), adding catecholamine vasopressors with $\beta_1$-adrenergic properties such as epinephrine to augment MAP in patients receiving norepinephrine is unlikely to prevent these tachyarrhythmias. In addition, epinephrine may preclude the use of lactate clearance as an initial resuscitation goal because epinephrine increases lactate concentrations through increased production by aerobic glycolysis (by stimulating skeletal muscle $\beta_2$-adrenergic receptors), an effect that likely wanes with continued epinephrine administration. It seems most prudent to use epinephrine in patients receiving norepinephrine with a
low MAP and requiring cardiac output augmentation. Dobutamine may be an acceptable option in this scenario as well.

Phenylephrine, essentially a sole $\alpha_1$-adrenergic receptor augmenter, is an attractive alternative for patients who develop tachyarrhythmias on norepinephrine. Because of its profound afterload augmentation effects (without $\beta_1$-adrenergic properties), phenylephrine may theoretically decrease stroke volume and cardiac output. As such, it is not recommended as a first-line vasopressor in patients with septic shock who have decreased cardiac output because of inadequate preload. A small study (n=32) that randomized patients with septic shock to phenylephrine or norepinephrine as first-line therapy found no difference in hemodynamic measures (including cardiac output) between agents in the first 12 hours of therapy. Evaluations of these data contrast the theoretical concerns with phenylephrine, which warrants further study in larger trials. The SSC guidelines recommend that phenylephrine be reserved for the patients with the following: (1) a tachyarrhythmia on norepinephrine, (2) a confirmed high cardiac output with a blood pressure that is still low despite use of norepinephrine, or (3) an unachieved goal MAP with other vasoactive agents, including low-dose arginine vasopressin.

Dopamine is best used in a select patient population, including patients with a low risk of tachyarrhythmias (which is difficult to predict) and those with bradycardia-induced hypotension. Low-dose (“renal dose” 2 mcg/kg/minute) dopamine should not be used to improve renal blood flow and urine output (renal protection).

Vasopressin

Arginine vasopressin offers an alternative mechanism of vasoconstriction to the $\alpha_1$-adrenergic receptor augmenting actions of catecholamines. Vasopressin constricts vascular smooth muscle directly (through actions on the $V_1$ receptor) and indirectly (by decreased nitric oxide–mediated vasodilation). In patients with septic shock, a relative vasopressin deficiency may exist, and patients are sensitive to the vasoconstrictive effects of arginine vasopressin. In light
of these effects, arginine vasopressin has been used in patients with septic shock as both an endocrine replacement therapy (with a fixed-dose infusion) and a vasopressor (titrated to MAP). A randomized trial compared the effects of adding arginine vasopressin (0.01–0.03 unit/minute) to norepinephrine with the effects of norepinephrine monotherapy. Overall, the study found no difference in 28-day mortality between treatment arms (35.4% vs. 39.3%, p=0.26), but norepinephrine requirements were significantly lower during the first 4 study days in the patients allocated to receive arginine vasopressin (p<0.001). There was no difference in adverse effects between groups. In an a priori–defined subgroup analysis of patients based on shock severity (less-severe shock defined as a baseline norepinephrine dose of 5–14 mcg/minute), with randomization stratified according to this covariate, 28-day mortality in the less-severe shock stratum was lower in patients randomized to arginine vasopressin plus norepinephrine (26.5% vs. 35.7%, p=0.05) and no different between groups in the more-severe shock stratum (44.0% vs. 42.5%, p=0.76, stratum interaction p=0.10).

To further investigate the effects of high-dose arginine vasopressin, a study of patients with vasodilatory shock (about half with septic shock) requiring high-dose norepinephrine (greater than 0.6 mcg/kg/minute) randomized patients to arginine vasopressin 0.033 unit/minute versus arginine vasopressin 0.067 unit/minute. The study was designed to evaluate hemodynamic changes, not mortality. Patients randomized to the higher arginine vasopressin dose had a more pronounced reduction in norepinephrine requirements than did those allocated to the lower arginine vasopressin dose (p=0.006). High-dose arginine vasopressin did not lead to a significantly lower cardiac index than did low-dose arginine vasopressin (as might be anticipated), but this finding is difficult to interpret because most patients in the study were receiving concomitant inotropes, and the study was likely underpowered to assess this outcome. Of note, however, large studies evaluating the efficacy and safety of high-dose arginine vasopressin have not been conducted, and this dosing strategy should be reserved for salvage therapy. In the setting of salvage
therapy, each additional therapy (e.g., phenylephrine, epinephrine, high-dose arginine vasopressin) has the potential for negative consequences, which the clinician should carefully consider during the therapeutic decision-making process.

Conflicting findings regarding the effects of arginine vasopressin (and its analogs) on mortality have been seen in meta-analyses. One meta-analysis found a decreased mortality risk in patients with septic shock allocated to arginine vasopressin (RR 0.87; 95% CI, 0.75–1.0; p=0.05), whereas another found no significant benefit with arginine vasopressin (RR 0.91; 95% CI, 0.79–1.05; p=0.21). Both meta-analyses found a significant benefit of arginine vasopressin in decreasing norepinephrine doses. Despite the unclear benefits of arginine vasopressin on mortality, this agent offers an alternative mechanism to catecholamines for vasoconstriction, and low-dose arginine vasopressin is commonly used in practice (often as the second vasoactive medication). In an ungraded recommendation, the 2012 SSC guidelines recommend adding arginine vasopressin (up to 0.03 unit/minute) to norepinephrine, with the intent of raising the MAP to goal or sparing norepinephrine.

Prospective randomized studies have shown no significant difference in the rate of adverse effects when catecholamine monotherapy was compared with the addition of arginine vasopressin to catecholamines. Similar to phenylephrine, arginine vasopressin is a pure vasoconstrictor and may decrease stroke volume and cardiac output. Thus, the previously mentioned randomized trial excluded patients with acute coronary syndrome or underlying chronic heart failure (New York Heart Association class III or IV). Vasopressin should be used with caution in patients with these disorders or with low cardiac output from other causes. Concerns for severe adverse effects (mainly cardiac arrest) from arginine vasopressin doses above 0.03–0.04 unit/minute have largely been based on retrospective, noncomparative reports when causality could not be established.

**Inotropes**

A low cardiac output is common in early septic shock, but this is often
corrected with fluid resuscitation alone. However, myocardial dysfunction may persist despite fluid resuscitation, with 39% of patients having left ventricular hypokinesia on ICU admission, despite fluid resuscitation, and an additional 21% with hypokinesia developing 24–48 hours after ICU admission (potentially attributable to norepinephrine) in one series.\textsuperscript{83} Patients with signs of hypoperfusion despite adequate cardiac filling pressures, MAP, and hemoglobin concentration should have an assessment of cardiac output (i.e., echocardiography, arterial pressure waveform analysis, or pulmonary artery catheterization). If myocardial dysfunction leads to significant impairment in oxygen delivery, an inotrope such as dobutamine may be indicated to improve cardiac output. Variable effects on systemic hemodynamics have been seen in studies of dobutamine administration in unselected patients with septic shock.\textsuperscript{84,85} Indeed, the SSC guidelines recommend that a trial of dobutamine infusion (up to 20 mcg/kg/minute) be administered or added to the vasopressor (if in use) only in patients with the presence of (1) myocardial dysfunction, as suggested by elevated cardiac filling pressures and low cardiac output; or (2) ongoing signs of hypoperfusion, despite adequate intravascular volume and adequate MAP. However, this recommendation is based on low-quality evidence. Dobutamine has commonly been used as a component of quantitative resuscitation to increase Scvo\textsubscript{2}; this approach must be individualized, and the decision to initiate dobutamine should include evidence of end-organ perfusion (e.g., elevated lactate concentrations and low urine output) as noted earlier.

**Corticosteroids**

For patients with septic shock, corticosteroids are an attractive treatment option because of their anti-inflammatory effects (through inhibition of NF-κB) and their ability to improve blood pressure response to catecholamines (through up-regulation of adrenergic receptors and potentiation of vasoconstrictor actions). However, using corticosteroids for patients with septic shock has been a source of controversy for many years. In studies of short courses of high-dose
corticosteroids in patients with severe sepsis and septic shock, corticosteroids did not lead to improved patient outcomes and may have increased mortality.\textsuperscript{86} Two large studies have evaluated the effects of longer courses of low-dose corticosteroids. In the first study, a French trial of patients with septic shock and vasopressor-unresponsive shock (i.e., inability to increase SBP greater than 90 mm Hg for 1 hour despite fluids and vasopressors), those randomized to low-dose hydrocortisone and fludrocortisone had improved survival in a time-to-event analysis (hazard ratio 0.71; 95% CI, 0.53–0.97) and time-to-shock reversal.\textsuperscript{87} The mortality benefit with corticosteroids was limited to patients unable to increase their cortisol concentration by more than 9 mcg/dL in response to adrenocorticotropic hormone administration (nonresponders). In the second study—the larger, multicenter Corticosteroid Therapy for Septic Shock (CORTICUS) study, which had less-stringent inclusion criteria—hydrocortisone administration was not associated with improved survival in adrenocorticotropic hormone nonresponders (28-day mortality 39.2\% vs. 36.1\%, \textit{p}=0.69).\textsuperscript{88} However, patient inclusion in the two trials was quite different, as shown by a placebo-arm 28-day mortality rate of 61\% in the French study\textsuperscript{87} and a corresponding mortality rate of 31\% in the CORTICUS study.\textsuperscript{88} These differences in patient characteristics suggest that severity of illness affects the benefit (or lack thereof) of corticosteroids in altering mortality in patients with septic shock.

In a meta-analysis of only high-quality trials, corticosteroid administration was not associated with improved survival in the overall analysis. When patients were analyzed according to severity of illness, a systematic review of three randomized controlled trials did not detect a mortality benefit with corticosteroid use in patients at a low risk of death (placebo mortality rate less than 50\%). In those with a high risk of death (placebo mortality rate greater than 60\%), there was a numerical, although not statistically significant, mortality benefit with corticosteroid use (RR 0.77; 95\% CI, 0.56–1.05).\textsuperscript{7} Another meta-analysis also found a significant relationship between severity of illness and patient outcomes with corticosteroids; low-dose corticosteroids were harmful in less severely ill patients and beneficial in more severely
ill patients. In meta-analyses, corticosteroid administration has consistently been associated with improvements in shock reversal, but, as noted previously, this has not led to a consistent benefit on patient mortality. These findings have further fueled the controversy regarding the role of corticosteroids in patients with septic shock. The SSC guidelines recommend that corticosteroids be used only in patients with septic shock who do not achieve resuscitation goals despite fluid resuscitation and vasopressors, but these guidelines do not explicitly define poor response to initial therapy. If a clinician were considering adding corticosteroids to decrease a patient’s mortality risk, it would seem prudent to initiate corticosteroids in severely ill patients. One approach to operationalize the SSC guideline recommendation is to reserve corticosteroids only for patients receiving norepinephrine doses greater than 40 mcg/minute (the mean maximal norepinephrine dose in the CORTICUS study was about this dose).

When corticosteroid use is deemed appropriate, hydrocortisone (without fludrocortisone) should be initiated immediately. Because of immunoassay imprecision and the inconsistent benefit of identifying patient response, the adrenocorticotropic hormone test should not be used to identify patients for corticosteroid administration. Unfortunately, the optimal dose, administration method, and therapy duration of hydrocortisone have not been fully elucidated. Although different hydrocortisone doses have not directly been compared in studies, 200 mg/day is now the dosage recommended by the SSC guidelines. Emerging data suggest that even this lower dose is too aggressive because of impaired hydrocortisone clearance in critically ill patients.

In low-level (grade 2D) recommendations, the SSC guidelines suggest that hydrocortisone be administered as a continuous infusion (rather than as a bolus injection) to avoid glucose fluctuations; the guidelines also suggest that hydrocortisone be tapered, to avoid rebound hypotension or inflammation, when patients no longer require vasopressors. Clinicians must balance the potential benefit of decreased glucose variability with the need for dedicated intravenous access and drug y-site incompatibility with a hydrocortisone infusion. In
addition, tapered doses will likely lead to longer treatment courses, and thus, adverse effects may occur more often with prolonged corticosteroid administration.

**SUPPORTIVE THERAPIES**

Drotrecogin alfa (activated), or recombinant human activated protein C, was used for more than a decade as the only therapy with a U.S. Food and Drug Administration–approved labeling for use in severe sepsis. However, clinical controversy regarding the risk-benefit ratio surrounded the agent, leading to the completion of another placebo-controlled phase III trial. Patients with septic shock and clinical evidence of hypoperfusion were randomized to receive a drotrecogin alfa or placebo infusion for 96 hours. There was no difference in 28-day mortality between the drotrecogin alfa and placebo groups (26.4% vs. 24.2%, p=0.31). Nonserious bleeding events were higher in patients allocated to drotrecogin alfa (8.6% vs. 4.2%, p=0.002); there was no difference between groups in the rate of serious bleeding.\(^\text{12}\) In light of these findings, the manufacturer of drotrecogin alfa voluntarily withdrew the agent from the market in October 2011.

Infusion of intravenous immunoglobulins in patients with severe sepsis and septic shock has the potential to neutralize bacterial antigens (e.g., endotoxin from gram-negative bacteria) and modulate the inflammatory response. However, randomized controlled trials and meta-analyses have yielded conflicting results regarding the effect of intravenous immunoglobulins on patient outcomes. Indeed, the largest randomized study of adult patients with severe sepsis did not detect a difference in 28-day mortality between patients allocated to intravenous immunoglobulin G or placebo (39.3% vs. 37.3%, p=0.67).\(^\text{90}\) However, a meta-analysis that analyzed the effect of immunoglobulin infusion in adults, children, and neonates found an association between immunoglobulin infusion and lower mortality (RR 0.79; 95% CI, 0.69–0.90; p≤0.0003).\(^\text{91}\) This meta-analysis did not use strict criteria to identify sources of bias and did not explicitly state the criteria used for assessing trial quality. In another meta-analysis, when only high-quality
studies were considered, there was no association between immunoglobulin infusion and mortality (RR 0.96; 95% CI, 0.71–1.30; p=0.78). However, there seems to be a difference in patient response between intravenous immunoglobulin preparations, with products containing immunoglobulins G, M, and A having superior benefits to those containing only immunoglobulin G. Of note, the intravenous immunoglobulin products available in the United States do not have immunoglobulin M, and they contain low levels of immunoglobulin A. In light of the conflicting data, the SSC guidelines suggest not using intravenous immunoglobulins for the treatment of patients with severe sepsis and septic shock.

TREATMENT PATHWAYS AND ORDER SETS

The SSC guidelines provide no explicit instructions for the timing and addition of particular pharmacotherapeutic agents for every patient. Instead, the approach should be individualized while incorporating the recommendations from guidelines and the data from the primary literature. A treatment pathway should provide the flexibility to initiate appropriate agents according to an assessment of altered hemodynamic parameters. Using an order set is one way to increase compliance with treatment pathways and guideline recommendations. Grouping of specific orders into an order set can help users operationalize the approach outlined in a treatment pathway.

Implementing order sets for the treatment of severe sepsis and septic shock can improve treatment processes and patient outcomes. In fact, several studies have noted increased volume of fluid administered within the first 6 hours of patient presentation, decreased time to antibiotic initiation, and even decreased mortality after order set implementation. Educating all patient caregivers regarding the components of the order set is essential to the success of the endeavor.

CONCLUSION
Severe sepsis and septic shock are associated with high patient mortality and morbidity. Optimal treatment of these patients is complex and requires frequent patient reassessment. Treatment of patients with severe sepsis and septic shock requires timely application of evidence-based therapies, as outlined in the SSC guidelines. Translating the literature and treatment principles described in these guidelines to bedside care while incorporating an assessment of patient-specific data is necessary to design a comprehensive pharmacotherapeutic care plan for the patient with severe sepsis or septic shock.

LEARNING OBJECTIVES

1. Classify intrinsic and acquired antifungal therapy resistance patterns for fungi.

2. Distinguish between antifungal interpretive breakpoints for Candida spp.

3. Develop an algorithm for selecting an appropriate antifungal therapy regimen based on current resistance patterns and risk factors for patients in a critical care setting.

INTRODUCTION

Invasive fungal infections (IFIs) from organisms including Candida spp., Aspergillus spp., and Rhizopus spp. represent a major burden of mortality and morbidity for patients in critical care settings.\textsuperscript{1-3} Although
new antifungal therapy options and rapid diagnostic testing capabilities for yeasts and molds have expanded treatment and prophylaxis options, knowledge of known risk factors for treatment efficacy based on fungi genus and species together with drug characteristics has become paramount to individualize antifungal therapy for patients admitted to intensive care units (ICUs)\textsuperscript{4,5}. Although several species of fungal organisms can be isolated from human culture samples, this chapter will focus on the common yeasts and molds that are known to cause IFIs in critically ill patients.

**Antifungal Therapy**

A variety of antifungal therapy options are available for the treatment of IFIs, but most are within three drug classes, as shown in Table 16.1, Table 16.2, and Table 16.3\textsuperscript{6-17}. Although many of the pharmacologic, pharmacokinetic, and pharmacodynamic properties within each of these drug classes are similar, several of the differences between the triazole agents may affect the selection of a drug for a critically ill patient with an IFI. Approved triazole agents with indications for fungal infections in the United States are fluconazole, itraconazole, isavuconazole (formulated as prodrug isavuconazonium sulfate), posaconazole, and voriconazole. Although these agents have a similar mechanism of action by inhibiting the cytochrome P450 (CYP)-dependent enzyme lanosterol 14-α-demethylase, there is significant variability in the spectrum of activity, drug characteristics, and appropriateness of use in patients who are critically ill, as shown in Table 16.2. All of these triazole agents are available in an intravenous formulation except for itraconazole in the United States. In patients with critical illness but adequate gastrointestinal (GI) function, each of these agents is available in oral formulations, although the delayed-release tablet posaconazole formulation should not be crushed and administered through feeding tubes. Conversely, the oral suspension posaconazole formulation that can be administered through a feeding tube can have significantly lower and unpredictable absorption compared with the delayed-release tablet formulation.\textsuperscript{18}
Antifungal Therapy Resistance Patterns

The in vitro interpretive criteria result for drug susceptibility testing should correlate with clinical outcomes and be associated with drug resistance mechanisms. Certain antifungal interpretive criteria were recently revised by the Clinical and Laboratory Standards Institute committee, as shown in Table 16.4. The revised susceptibility minimum inhibitory concentration (MIC) breakpoints for several Candida spp. were lowered because of recent studies evaluating the association of resistance mechanism, clinical outcomes, and reported MIC values. Interpretive criteria have not been established for antifungal agents for certain yeasts and molds because testing results have not clearly predicted clinical success and failure rates. A more detailed discussion of resistance mechanisms and antifungal therapy options for certain groups of yeasts and molds that are known to cause IFIs appears in the text that follows.

YEASTS

The two main types of yeasts that cause IFI in critically ill patients are Candida and Cryptococcus spp.

Candidiasis

Candida spp. are normal GI and oropharyngeal flora, but isolation from deeper sites and blood in a patient should not be ignored or considered a contaminant. Candida spp. isolated from blood requires appropriate antifungal treatment regardless of whether a visceral source is known. Conversely, 30%–50% of invasive Candida infections have negative blood cultures because of low sensitivity of traditional blood culture methods, so no growth from blood cultures does not exclude the diagnosis of a deep-seated Candida infection. Candida spp. endophthalmitis can occur from hematogenous seeding. An ophthalmologist examination is recommended for all patients with candidemia, and the presence of Candida endophthalmitis can increase the recommended antifungal therapy duration. If a patient is given a
diagnosis of Candida endocarditis, combined surgical and medical interventions should be considered. Conversely, pneumonia caused by Candida spp. is considered rare. Candida spp. isolated through respiratory samples such as sputum, tracheal, or bronchial lavage are normally considered a contaminant from normal oropharyngeal flora.\textsuperscript{21}

More than 200 Candida spp. have been known to cause medically significant disease.\textsuperscript{21} Although many Candida spp. have predictable susceptibility patterns, recent increased rates of acquired resistance to fluconazole and echinocandin agents for certain species may change treatment recommendations for IFIs, as shown in Table 16.5 and Table 16.6.\textsuperscript{4,22-31} Candida albicans isolates continue to have low antifungal therapy resistance rates and remain the most commonly isolated species even in ICU settings, but proportional rates of Candida spp. including C. glabrata, C. parapsilosis, C. tropicalis, and C. krusei with decreased susceptibility to fluconazole are changing.\textsuperscript{32,33} One of the associated risk factors for non-albicans candidemia in the ICUs (medical and surgical) at two U.S. tertiary care medical centers was previous fluconazole exposure (odds ratio [OR] 11.6; 95% confidence interval [CI], 2.3–58.9).\textsuperscript{34}

One study recommends a goal of 24-hour area under the curve (AUC24)/MIC of more than 400, which was associated with higher 30-day survival for patients with *C. albicans* but not non-*albicans* *Candida* bloodstream infections.

Depending on assay method. Separate measurement of active metabolite (hydroxyitraconazole) concentration can be considered if high-performance liquid chromatography (HPLC) is used instead of a bioassay.

Goal posaconazole serum concentrations have not been clearly established for the...
In addition to reduced susceptibility to fluconazole, the other main resistance concern for Candida spp. is reduced susceptibility to echinocandin agents from FKS gene mutations, which can decrease the amount of glucan synthesis available in the cell wall that is the binding site for echinocandin agents.\textsuperscript{35,36} FKS gene mutations are found in C. krusei and C. parapsilosis together with other Candida spp., but the prevalence of C. glabrata isolates with FKS1 or FKS2 gene mutation appears to be increasing, at least in certain geographic locations in the United States. Unlike with C. parapsilosis, the presence of FKS1 mutation in C. glabrata is associated with echinocandin treatment failures.\textsuperscript{37,38} In a single-center study at a U.S. tertiary care hospital, 18% of the C. glabrata bloodstream isolates from 2009 through 2012 had an FKS mutation.\textsuperscript{39} Echinocandin treatment failure occurred in 60% of patients with C. glabrata isolates with an FKS mutation compared with 23% of patients without an FKS mutation, and FKS mutations were associated with prior echinocandin exposure (OR 8.3; 95% CI, 1.7–40.4).\textsuperscript{39} In a prospective multicenter study in France, increased prevalence of non-albicans Candida spp. such as C. glabrata and C. krusei was associated with previous recent exposure to fluconazole (OR 2.17; 95% CI, 1.51–3.13), and Candida spp. with decreased susceptibility to caspofungin were associated with previous recent exposure to caspofungin (OR 4.79; 95% CI, 2.47–9.28).\textsuperscript{40}

Because there are known differences in susceptibility to antifungal agents for certain Candida spp., decreasing the time to species identification may decrease the time to appropriate antifungal therapy. As shown in Table 16.7, certain rapid diagnostic testing methods for specific yeasts are now being evaluated and approved for use in the United States by the U.S. Food and Drug Administration (FDA).\textsuperscript{5,41-50} Instead of waiting several days for species identification, some of these testing methods allow for direct testing of blood samples so that

d\textsuperscript{Mean isavuconazole trough concentration was 3 mcg/mL after 25 days of therapy}
Candida spp. identification can be reported on the day the blood sample was obtained. If a specific Candida spp. is isolated from blood or a deep site, susceptibility testing should be considered if few published data are found regarding susceptibility patterns or if there is significant risk of reduced susceptibility. To improve time to appropriate therapy, especially for Candida spp. with known acquired or intrinsic resistance to commonly used empiric antifungal therapy, a practitioner with knowledge of these patterns and the associated risk factors can use these testing methods to de-escalate or escalate antifungal therapy.

**Candidiasis Treatment**

The 2009 Infectious Diseases Society of America guidelines recommend echinocandins or fluconazole as an alternative regimen for empiric therapy in patients who are critically ill with suspected candidemia, depending on absolute neutrophil count. When this guideline statement was published, C. glabrata isolates were known to have clinically significant rates of reduced susceptibility and resistance to fluconazole. Since then, increasing rates of C. glabrata echinocandin resistance with and without co-resistance to fluconazole have been reported in the United States. Other antifungal therapy options may be considered if a patient has recent fluconazole and echinocandin exposure before isolation of C. glabrata because of concern for reduced susceptibility to these agents.

For Candida spp., cross-resistance for triazole agents may be best associated with fluconazole resistance. For Candida spp. with a fluconazole MIC of 64 mcg/mL or higher, there are increased rates of reduced susceptibility for itraconazole, isavuconazole, posaconazole, and voriconazole. For C. glabrata, fluconazole resistance is associated with reduced activity of posaconazole and voriconazole. In contrast, C. krusei is often susceptible to voriconazole despite being considered intrinsically resistant to fluconazole.

aParadoxical effect of resistance to killing may occur when higher-than-approved dosage is used that causes relatively high concentrations of echinocandin.

Multi-antifungal (fluconazole, echinocandin, and amphotericin B agents) resistance for Candida spp. has been reported in a few case reports and case series, but most of these cases involved patients who had prolonged periods of severe immunosuppression. Resistance to fluconazole and echinocandin agents is more common without resistance to amphotericin B agents. Therapy selection in these cases depends on susceptibility results, infection site, and each patient’s response to therapy.

Cryptococcosis

Cryptococcus neoformans is an encapsulated yeast that can cause IFIs in patients with significant immunosuppression (especially T lymphocytes) such as organ transplant recipients or patients with a diagnosis of AIDS, leukemia, or lymphomas. Patients often present to an acute care setting with symptoms consistent with chronic meningitis.

Cryptococcosis Treatment

In critically ill patients without a diagnosis of AIDS or history of an
organ transplant with central nervous system (CNS) or severe pulmonary cryptococcosis, amphotericin B deoxycholate with or without flucytosine is recommended for induction therapy that can be changed to fluconazole monotherapy for maintenance therapy. If the patient has a history of organ transplantation, the use of amphotericin B liposomal with fluconazole is recommended for induction therapy, followed by fluconazole maintenance therapy. For a patient with a diagnosis of AIDS and CNS cryptococcosis, amphotericin B deoxycholate with flucytosine or fluconazole is recommended. Maintenance therapy with fluconazole, itraconazole, or amphotericin B deoxycholate is recommended until the patient is asymptomatic and evidence of active disease has resolved.

*a* Candida spp. including C. albicans, C. glabrata, C. guilliermondii, C. krusei, C. parapsilosis, and C. tropicalis.

*b* MIC of 2 mcg/mL or higher is often associated with suboptimal efficacy.

*c* No breakpoints are available for C. krusei with fluconazole from the Clinical and Laboratory Standards Institute (CLSI). All isolates are considered resistant.

*d* No breakpoints are available for C. glabrata with voriconazole from CLSI.

---

**MOLDS**

Although not as common a cause of IFIs as Candida spp., several molds have been reported to cause IFIs with high morbidity rates and mortality. For certain mold species, antifungal therapy options
are limited.

**Aspergillosis**

Although Candida spp. are the most common cause of IFIs in ICUs, invasive Aspergillosis spp. infection rates have surpassed Candida spp. infection rates in patients with hematologic malignancy in the United States.\(^2,58\)

*aCases of amphotericin B–resistant isolates have been reported for Candida spp. including C. haemulonii (> 70%) and C. krusei.

*bCases of flucytosine-resistant isolates have been reported for Candida spp. including C. haemulonii, C. krusei (> 70%), C. pelliculosa, and C. utilis (> 50%).

Most Aspergillus spp. are reported to have low MIC values for commonly used therapy such as voriconazole and amphotericin B agents, but recent increases in resistance have been reported for specific species. A. terreus isolates tend to have high amphotericin B MIC values, whereas A. calidostus and A. lentulus isolates have reduced susceptibility to a variety of antifungal agents. Certain isolates of A. fumigatus have been reported to be resistant to voriconazole (TR46/Y121F/T289A mutation), itraconazole, and/or posaconazole, and higher mortality rates have been reported in patients infected with these isolates.59

Posaconazole, itraconazole, and isavuconazole all have potential efficacy for the treatment of invasive aspergillosis. In a noninferiority trial that compared isavuconazole with voriconazole, all-cause mortality rates through day 42 were 18.6% and 20.2%, respectively.60 Combination salvage therapy with an echinocandin and voriconazole or amphotericin B has been reported. The mortality rates of 47 patients
with invasive aspergillosis were significantly lower in patients who received voriconazole plus caspofungin than in those who received voriconazole mono-therapy (OR 0.28; 95% CI, 0.28–0.92).61

**Aspergillosis Treatment**

Voriconazole is recommended as monotherapy as first line because of a multicenter, randomized unblinded, clinical trial that compared the use of voriconazole with that of amphotericin B deoxycholate in patients with invasive aspergillosis.2 The voriconazole and amphotericin B group survival rates at 12 weeks were 70.8% and 57.9%, respectively (hazard ratio 0.59; 95% CI, 0.4–0.88).62 In critically ill patients with suspected invasive aspergillosis, initial use of an amphotericin B agent has been recommended to cover for both mucormycosis and aspergillosis until Aspergillus spp. infection has been confirmed, especially if the patient had recently received voriconazole.2,3

**Mucormycosis**

The rapidly growing organisms that cause mucormycosis (previously known as zygomycosis) include Absidia, Apophysomyces, Cunninghamella, Mucor, Rhizomucor, Rhizopus, and Saksenaea spp.3 The most common infection sites are rhino-orbital-cerebral or pulmonary in patients who are immunocompromised, received a diagnosis of diabetes, are intravenous drug users, or are receiving deferoxamine therapy for iron overload (enhanced growth of organisms). Although invasive Candida infection rates have decreased in patients with hematologic malignancies, rates of mucormycosis have increased. The use of voriconazole in this patient population has been associated as being an independent risk factor for disease (OR 10.4; 95% CI, 2.1–39).63

| Table 16.7 | Rapid Diagnostic Tools for Fungal Infections5,41-50 |
Mucormycosis Treatment

Primary treatment of mucormycosis is surgical intervention with early antifungal therapy together with decreasing immunosuppression or other risk factors, if possible.³ Appropriate early antifungal therapy within 6 days of diagnosis for mucormycosis is associated with decreased mortality rates (49% vs. 83%).⁶⁴ Lipid formulations of amphotericin B are used for initial therapy. Double coverage with posaconazole or isavuconazole is controversial because of the high mortality rate for patients with mucormycosis who receive amphotericin B monotherapy and the potential antagonism with triazole therapy. Before FDA approval of the labeled uses of the delayed-release tablet and intravenous formulations of posaconazole together with the oral and intravenous formulation of isavuconazole, the oral suspension formulation of posaconazole was used for the treatment of mucormycosis.
According to posaconazole 24-hour area under the curve comparison, the bioavailability of the delayed-release formulation of posaconazole is higher than that of the oral suspension, so the tablet formulation may be preferred for mucormycosis treatment.\textsuperscript{18} Isavuconazole has an FDA-approved indication for the treatment of invasive mucormycosis. In an open-label study of isavuconazole for patients with probable or proven mucormycosis, the all-cause mortality rate was 47\% at day 180.\textsuperscript{65}

Echinocandin agents in combination with amphotericin B products have been reported.\textsuperscript{66} Echinocandin agents have no in vitro activity against the organisms that cause mucormycosis. One retrospective study evaluated 41 patients with rhino-orbital or rhino-orbital-cerebral mucormycosis. Six of the 41 patients received a combination of caspofungin and amphotericin B agents, whereas the remaining patients received monotherapy with amphotericin B.\textsuperscript{66} Using multivariate logistic regression analysis with an end point of success at 30 days after hospital discharge, the combination therapy patient group had higher success rates (OR 10.9; 95\% CI, 1.3–\infty).

**Scedosporiosis**

Scedosporiosis is associated with high mortality rates in immunocompromised patients, and infection outcomes are associated with the immune function of patients and surgical interventions.\textsuperscript{56}

**Scedosporiosis Treatment**

Antifungal susceptibility testing is recommended because of variable reported resistance to Scedosporium spp.\textsuperscript{55} Voriconazole is often used as the primary antifungal agent for infections caused by S. apiospermum (asexual form of Pseudallescheria boydii). Therapy options are limited for S. prolificans because high antifungal MIC (amphotericin B, flucytosine, triazole agents) and minimum effective concentration (echinocandin) values have been reported for most isolates. Combination therapy of voriconazole with micafungin,
miltefosine, or terbinafine based on in vitro synergy testing has been reported.

**Fusariosis**

Certain *Fusarium* spp. have been reported to cause IFIs with high mortality rates in immunocompromised patients, especially those with a T-cell immunodeficiency or severe neutropenia. Treatment successes are associated with improved outcomes with immune reconstitution. Agents such as interferon-γ and granulocyte colony-stimulating factor have been prescribed to patients with invasive fusariosis, but efficacy rates with these types of agents are not fully understood.

**Fusariosis Treatment**

High MIC values have been reported for a variety of anti-fungal agents including echinocandin and amphotericin B agents with *Fusarium* spp. and triazole agents, specifically with *F. solani* and *F. verticillioides*. Despite in vitro results, lipid formulations of amphotericin B and/or voriconazole have been used to treat invasion fusariosis, with 90-day survival rates reported as 28%–53% with amphotericin B agents and 60% with voriconazole. Posaconazole has been used as salvage therapy, whereas combinations of amphotericin B agents with caspofungin, terbinafine, or voriconazole have been reported.

---

**DIMORPHIC FUNGI—OPPORTUNISTIC ENDEMIC FUNGAL INFECTIONS**

Some fungi are dimorphic because these organisms can grow as either a mold or a yeast, depending on growth conditions. Many of the dimorphic fungi that cause IFIs in critically ill patients are considered endemic to certain geographic locations. *Blastomyces dermatitidis*, *Coccidioides* spp., and *Histoplasma capsulatum* may be causative organisms of IFIs, depending on a patient’s exposure history in the United States. Treatment of endemic IFIs depends on the site and
severity of disease together with patient characteristics. Amphotericin B or triazole (including fluconazole or itraconazole) is commonly used as first-line therapy.

**Treatment of Blastomycosis**

Pulmonary blastomycosis is commonly treated with itraconazole or amphotericin B, as recommended by the 2008 Infectious Diseases Society of America guideline statement. Therapy recommendations start with amphotericin B agents rather than itraconazole for severe disseminated blastomycosis.

**Treatment of Coccidioidomycosis**

Endemic to the U.S. Southwest, *Coccidioides* spp. infections often need no treatment. Most patients will be asymptomatic after initial exposure. Pulmonary or disseminated disease can develop in some infected patients. Amphotericin B agents are often used first line for symptomatic critically ill patients, with fluconazole or other triazole agents used as stepdown therapy or as initial therapy for less severe disease. If a patient is given a diagnosis of meningitis, fluconazole or alternative triazole therapy is normally recommended to be continued for the duration of the patient’s life because of high relapse rates if triazole therapy is discontinued. For refractory cases, other triazole agents have been prescribed, but comparison data are limited. Interferon-γ has been used in salvage therapy in combination with antifungal therapy for patients with interferon-γ receptor 1 deficiency.

**Treatment of Histoplasmosis**

Infection with *H. capsulatum* is often asymptomatic, but certain critically ill patients, especially if immunocompromised, may require antifungal therapy. As discussed in the 2007 Infectious Diseases Society of America guideline statement, amphotericin B is often used as first-line therapy for moderate to severe pulmonary histoplasmosis, and
methylprednisolone can be prescribed in combination if the patient develops acute respiratory distress syndrome. Itraconazole can be used as outpatient therapy.

PROPHYLAXIS FOR IFIs

As shown in Table 16.8, patients in a critical care setting can have a variety of risk factors that have been associated with the increased invasive Candida infection rates, including degree of immunosuppression, exposure to broad-spectrum antibiotics, parenteral nutrition, and use of devices including dialysis and extracorporeal life support.21,33,71-74 The use of antifungal prophylaxis and screening tests such as (1,3)-beta-d-glucan or galactomannan antigen detection assays has been evaluated for patients with certain risk factors for the prevention and detection of IFIs.75-78 Please see chapter 13, “Laboratory Testing Considerations”; chapter 18, “Antimicrobial Prophylaxis”; and chapter 50, “Care of Immunocompromised Patient,” for specific information regarding fungi screening assays and antifungal prophylaxis in critically ill patients.

CONCLUSION

Specialists with a knowledge of antifungal therapy pharmacology and pharmacokinetics together with interpretive susceptibility breakpoints can influence the appropriate use of these agents in patients with IFIs in critical care settings. As yeast and mold rapid diagnostic detection advances, practitioners’ ability to develop antifungal therapy algorithms and protocols for drug selection and monitoring on the basis of therapy outcomes, patient characteristics, and known resistance patterns will become important to decrease the time to appropriate antifungal therapy.

| Table 16.8 | Risk Factors for Invasive Candida Infections | 21,33,71-73 |
Infection Site | Associated Risk Factors Include
---|---
General risk factors for invasive infection | Immunocompromised state (hematologic malignancies, HSCT, solid organ transplantation, corticosteroids), central venous catheters, parenteral nutrition, exposure to broad-spectrum antibiotics, renal dysfunction (acute), diabetes, surgical procedures

Specific risk factors based on diagnosis:

Bloodstream infection (candidemia) | • ICU admission

Empyema | • Candidemia

Endocarditis | • Prosthetic heart values, intravenous drug use, central venous catheters, prolonged candidemia

Meningitis | • Candidemia

Pericarditis | • Candidemia, thoracic surgery

Peritonitis | • Peritoneal dialysis, GI perforation, anastomotic leaks, acute necrotizing pancreatitis

HSCT = hematopoietic stem cell transplantation; ICU = intensive care unit.

3. Cornely OA, Arikan-Akdagli S, Dannaoui E, et al. ESCMID and

exposure to micafungin and caspofungin in a BM transplant unit. Bone Marrow Transplant 2015;50:158-60.

LEARNING OBJECTIVES

1. Describe and familiarize the reader with viral infections that may be present in the intensive care unit (ICU).
2. Discuss typical patient presentations of these viral infections.
3. List standard diagnostic tools used to differentiate typical viral infections in ICU patients.
4. Recommend appropriate pharmacologic therapy for common viral infections in the ICU.

INTRODUCTION

Viruses play a predominant role in many infectious-related hospital admissions ranging from mild gastroenteritis to life-threatening meningoencephalitis. Intensive care unit (ICU) admissions are also commonplace both in acute viral infections (e.g., respiratory, encephalitis) and among those with chronic infections including HIV and hepatitis. The emergence of viral hemorrhagic fevers (VHFs) and vaccine-preventable diseases such as measles is becoming more prevalent in recent times, requiring new therapeutic advances and renewal of once-forgotten therapies. Many patients admitted to the ICU with viral infections will require mechanical ventilation, vasopressor support, and further invasive management. Although viral pathogens are probably community acquired, there are several reports of hospital
acquisition of enteric pathogens such as rotavirus and norovirus, influenza, and cytomegalovirus (CMV).\textsuperscript{2,3} Many hospital-acquired infections can be limited through proper education combined with continued hand hygiene, appropriate employee vaccination, and early recognition of a potential outbreak.\textsuperscript{3-5}

Although significant, morbidity and mortality vary depending on the viral pathogen and the underlying immune status of the host. The increasing burden of viral disease in hospitalized patients, especially among immunocompromised hosts, has concurrently increased the need for and value of early diagnosis.\textsuperscript{6,7} Molecular-based rapid diagnostics such as nucleic acid amplification tests, which are becoming more readily available, allow for early identification of viral pathogens.\textsuperscript{8,9} Although causality cannot always be established because of the limitations of such tests, they can help direct targeted pharmacotherapy and promote antimicrobial stewardship in combination with additional laboratory assessment and clinical correlation. Pharmacologic therapy includes not only direct antiviral therapy, but also supportive care measures including hemodynamic management, corticosteroids, and management of common sequelae such as seizures, acute kidney injury, and post-viral bacterial infections. Despite their effectiveness, many antivirals are associated with significant adverse drug events and require careful monitoring. Continuing of home medications for chronic viral infections, specifically HIV, is essential to avoid the development of resistance and an iatrogenic nonadherence.\textsuperscript{10} In addition, challenges in drug administration and dosing are created with ICU patients, with frequent interruptions in oral access, intravenous compatibility issues, dynamic renal function, and altered pharmacokinetics.\textsuperscript{10} This chapter discusses the clinical presentation, diagnoses, and management of both the common and emerging viral infections seen in the ICU.

**HUMAN HERPES VIRUS**

The Herpesviridae is a family of double-stranded DNA viruses with eight distinct varieties identified as human pathogens. Exposure to
these endemic viruses is common, and transmission is often through sexual contact such as with herpes simplex virus (HSV) or casual contact with Epstein-Barr virus (EBV).\textsuperscript{11} Although infections in immunocompetent hosts are common, underlying immunocompromise from malignancy, solid-organ or blood and marrow transplantation, or HIV places patients at a heightened risk of invasive herpes infections.\textsuperscript{12} In addition to HSV-1 and HSV-2 infections, other important invasive human herpes viruses in hospitalized patients include CMV and varicella zoster virus (VZV).

**Herpes Simplex Virus Types 1 and 2**

Herpes simplex virus exposure in the general population occurs commonly at an early age with an 80\%–90\% seropositivity rate.\textsuperscript{13} Herpes simplex virus type 1 preferentially establishes latency in the trigeminal ganglion near the ear, typically causing oral lesions, whereas HSV-2 primarily establishes latency in the sacral ganglion at the base of the spine, leading to genital infections. Transmission is through direct contact, by the oral or genital route.\textsuperscript{14} Although many infections secondary to HSV are often superficial, HSV is responsible for invasive diseases including meningoencephalitis and, less commonly, pneumonia. Herpes simplex virus is the most prevalent pathogen in encephalitis, identified in 40\%–50\% of encephalitis cases with a known cause and in about 20\% overall.\textsuperscript{1,15,16} Table 17.1 provides an overview of viral causes of encephalitis. Although HSV-2 may cause aseptic meningitis, HSV-1 is the predominant type in encephalitis cases. The incidence does not appear to change significantly on the basis of age or sex.\textsuperscript{1,13}

Mumps, measles
Universally, patients with viral encephalitis present with altered mental status, although coma is less common, occurring in about 25% of patients with HSV. For coma to occur, there must be significant cerebral edema raising intracranial pressure or disruption of the ascending reticular activating system (RAS), a neuronal network responsible for wakefulness.\textsuperscript{17} Disruption of the RAS is especially common with the temporal lobe involvement seen with HSV encephalitis. Fever occurs in more than 75% of patients. Overt seizures have been reported in up to 65% of patients; however, encephalitis in general is among the most common cause of nonconvulsive status epilepticus, which can only be reliably diagnosed with electroencephalogram (EEG). Seizures are an independent predictor of worse outcomes, and chronic epilepsy is common after treatment.\textsuperscript{18,19} Diagnosis is achieved through radiology, cerebrospinal fluid (CSF) examination after lumbar puncture, and CSF polymerase chain reaction (PCR) for HSV. Magnetic resonance imaging (MRI) is abnormal in 90% of cases, whereas computed tomography (CT) scans are abnormal more than 50% of the time. On CSF examination, patients typically have a predominance (80%) of lymphocytes with elevated protein. The presence of red blood cells or xanthochromia may be caused by hemorrhagic inflammation secondary to HSV. Serologic testing is unhelpful, and the test of choice is PCR on the CSF. The sensitivity, which is about 100%, may decrease slightly over time if obtaining CSF is delayed for several days. Viral culture has a low sensitivity and is not commonly performed in standard laboratories.\textsuperscript{20,21}

According to several randomized controlled trials (RCTs), antiviral therapy with intravenous acyclovir should be initiated empirically if HSV is in the diagnostic differential (\textit{Table 17.2}).\textsuperscript{22,23} Acyclovir is activated
by the viral enzyme thymidine kinase, present in essentially all strains of HSV. Therapy delays beyond 2 days have been associated with poorer outcomes, and initiation within the first 48 hours of suspicion has resulted in reduced mortality rates below 10%.\textsuperscript{24} Acyclovir is typically dosed on ideal body weight, although this recommendation is based on very limited data.\textsuperscript{25} Associated toxicities commonly include nephrotoxicity and, less commonly, headache, gastrointestinal (GI) effects, altered mental status, and bone marrow suppression. The mechanism of nephrotoxicity is thought to be obstructive secondary to the crystallization of acyclovir in the renal tubules exceeding maximum solubility. Intravenous hydration is an important mechanism of prevention and should be initiated in critically ill patients. Rapid administration may also contribute to the development of acute kidney injury.\textsuperscript{10} Therapy duration is typically 14–21 days, despite the original RCTs targeting 10 days of therapy,\textsuperscript{24} because of the long-term neuropsychological effects commonly seen among survivors. A recent trial of extended 3-month therapy with oral valacyclovir showed no improved outcomes compared with placebo; however, the rate of neuropsychological decline in this population was less than 15%, lower than in previous reports.\textsuperscript{26} Oral valacyclovir, a prodrug of acyclovir, has excellent bioavailability and, at doses of 1,000 mg every 8 hours, has shown sustained CSF concentrations above target during a 20-day treatment period.\textsuperscript{27,28} Although treatment data are limited, this may be a potential option when intravenous access or intravenous acyclovir is unavailable. Rarely, HSV has tolerance or resistance to acyclovir, primarily because of deficiency or mutations in thymidine kinase. In these cases, alternative antiviral therapies, including foscarnet or less commonly cidofovir, should be considered. Ganciclovir, a thymidine kinase–dependent antiviral, should not be used routinely in suspected acyclovir resistance or clinical failures.\textsuperscript{11} Foscarnet and cidofovir dosing is available in Table 17.2 and discussed in more detail in the Cytomegalovirus section.

Comprehensive symptomatic care is also important for these patients to prevent secondary brain injury, including management of hypotension, hypoxemia, intracranial hypertension, hyperthermia, hypo-
and hyperglycemia, anemia, and seizures.\textsuperscript{1} Adjunctive use of corticosteroids, specifically dexamethasone, was studied in a limited fashion in a single study of 45 patients with HSV encephalitis.\textsuperscript{29} Although corticosteroids were a predictor of improved outcomes in combination with acyclovir, they are not routinely recommended at this time. Management of status epilepticus in accordance with current national guidelines is initially with intravenous lorazepam and establishment of a second agent to prevent recurrence, which may include one of several intravenous options including phenytoin, fosphenytoin, valproate, levetiracetam, and lacosamide.\textsuperscript{30}

**Cytomegalovirus**

Cytomegalovirus is a large double-stranded type 5 β-herpesvirus most closely related to human herpesviruses 6 and 7.\textsuperscript{6} Viral replication takes place in human fibroblasts and can be found in an array of cell types including hematopoietic cells, epithelial cells, endothelial cells, fibroblasts, and smooth muscle cells.\textsuperscript{31} Similar to other herpesviruses, CMV remains latent in the human body after primary infection and may reactivate throughout a host’s life span, causing severe disease in immunocompromised individuals. Asymptomatic viral shedding (urine, saliva, semen, breast milk, and cervical secretions) continues after primary infection; the virus is passed from the infected host through direct contact with body fluids, including sexual contact, blood transfusions, and transplanted organs, with oral and respiratory secretions being the primary route of transmission.\textsuperscript{32,33}

*Note: IBW = Ideal body weight, CrCl = Creatinine clearance, SCr = Serum creatinine*
Cytomegalovirus causes complications in the fetus, neonate, and immunocompromised host but rarely in the healthy adult. The Centers for Disease Control and Prevention (CDC) reports that 50%–80% of all adults within the United States are infected with CMV by age 40. About 1% of infants are congenitally infected in the United States. Cannon and colleagues found a higher seroprevalence of 45%–100% among women of reproductive ability. Seronegativity within this population places patients at risk of primary infection while pregnant. Variation exists in seropositive percentages across the United States.

In the immunocompetent host, children and adults may be asymptomatic. However, CMV often presents similar to a mononucleosis-like syndrome, comparable with that caused by EBV. Cytomegalovirus causes host-dependent diseases, resulting in immunocompromised hosts developing invasive disease. Specifically in the immunocompromised host, CMV often presents with end-organ damage (e.g., colitis, esophagitis, and neurologic diseases). Solid-organ transplant recipients may have CMV-associated leukopenia, and bone marrow recipients often present with interstitial pneumonitis or pneumonia. In severely immunocompromised patients with AIDS, disease manifestations include gastroenteritis and chorioretinitis leading to potential blindness. Cytomegalovirus retinitis is the most common HIV-associated CMV infection and usually presents at CD4 counts below 100 cells/mm³. Acute flares may be associated with initiating
highly active antiretroviral therapy (HAART) against HIV correlating with an immune reconstitution syndrome.

Cytomegalovirus viremia is detected primarily by PCR, although antigen assays and culture are also available. End-organ disease should not be diagnosed by CMV antigen because of the potential for false-negative tests. Antibody presence in breast milk does not confer protective immunity but may defend against serious disease in the newborn. Antibody titers during acute and chronic illness are usually performed with enzyme immunoassays and indirect and anticomplement immunofluorescence assays. The CMV-immunoglobulin (Ig)M test is highly sensitive but is restricted because of the cross-reaction of acute EBV and the presence of rheumatoid factors. A 4-fold increase in serologies is used to assist in diagnosing infection; however, false positives may occur, and serology testing should not be used alone. Cytomegalovirus may be detected in a blood, urine, throat, and lung culture (from bronchoalveolar lavage or washing) as well as in a lung biopsy. The tissue culture method (shell vial assay) involves centrifugation and an immunocytochemical detection, which uses monoclonal antibodies directed at early CMV antigen.

In the solid-organ transplant recipient, CMV is one of the most important pathogens causing significant morbidity and mortality posttransplantation. More than 50% of solid-organ transplant recipients show evidence of CMV infection. The serostatus of the recipient and donor determines the response after transplantation. The patient with the strongest risk of infection and invasive disease is a serologically negative recipient receiving an organ from a serologically positive donor. However, CMV infection in hematopoietic stem cell transplant recipients is primarily through reactivation of a latent virus of a seropositive recipient. Infection can occur if the recipient or donor is serologically positive; however, the disease severity is lessened. The T cell–mediated immune response primarily controls CMV replication, placing immunodeficient hosts at higher infection rates. Cytomegalovirus pneumonitis is rare together with pneumonia, but it represents the most troublesome infection in this patient population, which presents with fever, cough, and infiltrates on chest radiography.
Clinicians prefer to see diagnostic “owl’s-eye” inclusion bodies on lung biopsy for confirmation.\textsuperscript{7,35}

The widespread use of HAART in the United States against HIV has led to a decreased prevalence of CMV retinitis within this population. Retinitis is still the most common CMV-associated end-organ disease and often presents unilaterally. Bilateral progression occurs without appropriate therapy or recovery of the immune system.\textsuperscript{7} Cytomegalovirus retinitis affects populations discordantly; men who have sex with men have a higher rate of latent infection, with estimates as high as above 90\%.\textsuperscript{37}

Therapy for CMV-associated infections should be individualized.\textsuperscript{38} Location and severity of infection should be considered before initiating therapy. Primary treatment with ganciclovir (or valganciclovir) is indicated in patients with confirmed, invasive disease. Foscarnet and cidofovir are alternative therapeutic regimens. Patients with HIV infection remain on secondary prophylaxis until CD4 counts recover to greater than 100 cells/mm\textsuperscript{3} for 3–6 months.\textsuperscript{7,38} Patients receiving solid-organ or bone marrow transplants usually receive prophylaxis for about 3 months.

Ganciclovir requires triphosphorylation to a substrate that competitively inhibits viral DNA synthesis by inhibiting the binding of deoxyguanosine triphosphate to DNA polymerase. The first phosphorylation is known as the rate-limiting step and is induced by enzymes produced by CMV. This unique mechanism renders acyclovir inactive against CMV. The oral prodrug of ganciclovir, valganciclovir, is commonly used in CMV infections. Valganciclovir is rapidly converted to ganciclovir and has about 60\% bioavailability. Both agents are renally dose adjusted and require close monitoring.\textsuperscript{7,39,40} The predominant adverse effects are moderate to severe neutropenia followed by thrombocytopenia and central nervous system (CNS) events such as confusion and dizziness. Fever and GI adverse events are also documented. Valganciclovir adverse drug events include hypertension, headache, insomnia, and tremor, which are more associated with the use of valganciclovir than with ganciclovir. Cerebrospinal fluid concentrations of ganciclovir are about 50\% of serum concentrations.
This agent should be continued and monitored closely as maintenance therapy after induction is complete, given the high relapse rates if prematurely discontinued. Ganciclovir may also be administered intraocularly every 5–8 months for CMV retinitis.\textsuperscript{7,39,40}

Foscarnet is a pyrophosphate analog that acts as a non-competitive inhibitor of many viral RNA and DNA polymerases as well as HIV reverse transcriptase. Foscarnet is a highly toxic agent causing considerable nephrotoxicity and electrolyte disturbances (hypomagnesemia, hypokalemia, hypocalcemia). Aggressive hydration is used to decrease renal toxicity, and appropriate dose adjustments must be made in patients with preexisting renal dysfunction. An infusion pump, at a rate not to exceed 1 mg/kg/minute, is necessary for administration. Other documented adverse events are genital ulcers, dysuria, nausea, and paresthesia. This agent does not require phosphorylation to be active; therefore, it can be used to treat ganciclovir-resistant isolates.\textsuperscript{7,41}

Cidofovir acts through inhibition of viral DNA synthesis by incorporating cidofovir into replicating viral DNA. Infusion must take place over 1 hour with 1 L of 0.9% normal saline administered intravenously before cidofovir infusion. A second liter may be administered over 1–3 hours immediately after infusion, if tolerated. Serum creatinine (SCr) must be monitored for dose adjustments, and contraindications to cidofovir include SCr values greater than 1.5 mg/dL, creatinine clearance greater than 55 mL/minute/1.73 m\textsuperscript{2}, history of clinically severe hypersensitivity to probenecid or other sulfonamide-containing medications, and use of nephrotoxic agents within 7 days. Although renal toxicity is the primary adverse effect of cidofovir administration, GI, hematologic (black box warning for neutropenia), and CNS effects have been reported.\textsuperscript{42,43}

**Varicella Zoster Virus**

Varicella zoster virus is a human neurotropic DNA virus. Primary varicella infection or chickenpox was once commonplace in children in the United States until the vaccine was licensed in 1995. The causative
agent, VZV, remains latent in the cranial nerve, dorsal root, and autonomic ganglia along the entire neuroaxis. More than 90% of adults are latently infected with VZV.\textsuperscript{44} With the decline in VZV cell-mediated immunity, reactivation occurs in older adults, especially those older than 85 years, and in those with severe immunocompromise, including organ transplantation, malignancy, and HIV.\textsuperscript{1,44} Reactivation may occur at any point during the immunocompromised state, although it has been the presenting condition before an HIV diagnosis. On reactivation, herpes zoster presents classically as a vesicular rash after dermatomes with sharp, radiating pain exacerbated by touch. Varicella zoster virus is also the most common cause of viral encephalitis in immunocompromised hosts. Other systemic manifestations include cerebellitis, meningoencephalitis, myelopathy, and ocular disease. Ocular involvement usually manifests as acute retinal necrosis or progressive outer retinal necrosis, of which VZV is the most common cause. This typically occurs in patients with HIV and a CD4 count less than 10 cells/mm\textsuperscript{3}. Varicella zoster virus infection in the cerebral arteries often leads to ischemic or hemorrhagic stroke.\textsuperscript{45-47} Postherpetic neuralgia is also extremely common.

Vasculopathy is a common theme in patients with systemic varicella CNS disease, and some investigators have argued that most VZV CNS infections represent vasculopathy as opposed to encephalitis. Patients may have both small and large vessel involvement. Although most patients will develop CNS involvement after zoster, up to 33% of patients will develop encephalitis in the absence of rash.\textsuperscript{45,46,48} In addition, MRI scans are abnormal in most cases; however, some changes on CT and MRI can be seen in patients with rash in the absence of neurological changes. Patients who present with transient ischemic attack or ischemic stroke, chronic headaches, or severe altered mental status with a history of zoster should be evaluated for VZV CNS disease. In addition, those with severe immunocompromise with or without preceding zoster should be evaluated for VZV disease when other common causes of altered mental status have been ruled out. Compared with HSV encephalitis, however, milder CNS-specific symptoms and fever should be expected.\textsuperscript{1,44}
Together with imaging findings, patients with confirmed disease will have a CSF pleocytosis in approximately 66% of cases. Angiography has revealed abnormal findings in 70% of patients. With a high specificity, VZV PCR on CSF may be the initial diagnostic test, but with a low sensitivity, a negative PCR can be seen in up to 70% of patients. Anti-VZV IgG in the CSF is present in more than 90% of patients with active CNS infection and should be considered the optimal diagnostic test. Patients in the ICU are less likely to have VZV optic disease because of the protracted disease course; however, it may occur concomitantly with CNS disease.

Recommended management of invasive VZV disease is intravenous acyclovir 10–15 mg/kg every 8 hours. Compared with HSV, higher doses of acyclovir may be required because targeted concentrations against VZV are relatively higher in some strains. Controlled trials supporting this recommendation are limited; however, reduction in disease severity and recovery time has been shown. Therapy should not be delayed because of lack of confirmed diagnostics from CSF if suspicion of VZV is high. Many patients will have concomitant immunocompromising states (e.g., malignancy and HIV) that require management of these conditions. Toxicities associated with acyclovir, which are often dose-dependent, remain significant and may be exacerbated in immunocompromised patients with underlying renal dysfunction. Therapy duration should be 14 days; however, 21 days should be strongly considered in patients with underlying immunocompromise. Use of oral agents such as valacyclovir has not been studied and cannot be recommended at this time. Because of the accompanying vasculitis, adjunct corticosteroids are recommended by many experts. A prednisone equivalent dose of 1 mg/kg/day should be considered. Limited use in varicella pneumonia has had some beneficial effects. No definite duration for prednisone has been established, although some have recommended 3–5 days of therapy. Short-course therapy may still be associated with significant adverse drug events and should be evaluated and managed as required. In patients with VZV optic disease—specifically, progressive outer retinal necrosis—acyclovir monotherapy has produced suboptimal results. Ganciclovir
or foscarnet, or in combination, should be considered first-line therapy. Dosage is consistent with that of other invasive viral diseases (Table 17.2). Because of the immunocompromised state of many of these patients, specialist management, including infectious diseases consultation, is recommended. Although many patients recover from the VZV infection itself, full recovery is highly dependent on disease manifestations (e.g., stroke) and the patient’s immune status.44

Epstein-Barr Virus

Epstein-Barr virus is commonly known as the causative pathogen of infectious mononucleosis. Although it can rarely be responsible for other invasive viral syndromes in immunocompetent hosts, including encephalitis, most patients at risk of EBV disease are severely immuno-compromised. Epstein-Barr virus is primarily transmitted through saliva.52 In immunocompetent hosts, EBV preferentially infects circulating B lymphocytes and the epithelium in the oropharynx and of the cervix. These infected B lymphocytes lead to infiltration of other organs. The lymphocytosis seen with EBV infection is primarily that of T lymphocytes, indicative of the extreme immune response mounted against infected B cells.52,53 In immunocompromised hosts, especially those with HIV/AIDS and those after solid-organ or blood and marrow stem cell transplantation, EBV is responsible for many infections including hairy leukoplakia (HLP), lymphoproliferative syndromes, and several associated malignancies. In HLP, EBV replicates at high numbers in associated lesions; however, EBV remains in a latent state in other associated syndromes and malignancies.53

Treatment of these patients is targeted at restoring T-cell (and B-cell) immune function and supportive care. Antiviral therapy, including acyclovir, has activity in vitro; however, clinical trials have failed to show morbidity or mortality benefit.54,55 This may be because of a lack of phosphorylation, and thus activation, of the antivirals by viral enzymes. In addition, failure to concentrate in circulating infected B lymphocytes and inability to target the virus in the latent state may be contributing factors. Corticosteroids are used in the acute phase of these infections
by some experts, although clinical data to support outcomes are lacking.\textsuperscript{1,55}

\textbf{HUMAN IMMUNODEFICIENCY VIRUS}

Establishment of HIV infection depletes the T lymphocytes and therefore promotes an immunosuppressive state. About 3–6 weeks after an initial HIV infection, more than half of infected individuals experience an acute HIV infection syndrome.\textsuperscript{56} The term acute refers to the time during which the virus is detectable within the blood and serum but antibodies have not yet formed.\textsuperscript{57} Symptoms vary in severity but resemble an acute infectious mononucleosis. The decrease in CD4 T lymphocytes and the perpetual increase in viral load lead to the acute HIV response. After this response, described in further detail in the following text, an immune response will mount from the host in an attempt to fight the infection. The immunity formed from the host does not completely hinder viral replication, and the decrease in viremia does not persist.\textsuperscript{58,59} Immunity is decreased by the infected CD4 T lymphocytes, and opportunistic infections are most common at CD4 T-cell counts less than 200/mm\textsuperscript{3}. To prevent this progressive decrease in immune function, the mainstay of treatment is initiating antiretroviral therapy.\textsuperscript{60}

During initial HIV infection, patients often present with fever, pharyngitis, lymphadenopathy, headache, muscle pain, fatigue, weight loss, and GI symptoms (nausea, vomiting, and diarrhea). Patients may also have a maculopapular rash on the trunk and extremities and/or genital ulcers. Presentation with sexually transmitted infections (HSV, gonorrhea, syphilis, hepatitis viruses) is common, and coinfection rates are high. This nonspecific syndrome leads to a diagnostic challenge for clinicians. Antibody formation is undetectable on initial infection and may not be present during the acute infectious stage. Acute HIV is therefore often undiagnosed, leading to negative patient outcomes and necessitating high clinical suspicion.\textsuperscript{58,59}

On entry into the health care system, it is recommended that all patients be tested for HIV with an opt-out setting. Initial HIV infection
presents with a high viral load, and patients may not know they are infected. Rosenberg and colleagues found that early treatment with antiretrovirals increased HIV-1–specific CD4 and CD8 T-cell responses, boosting host immunity.\textsuperscript{60}

Initiating HAART may precipitate an immune reconstitution inflammatory syndrome (IRIS), often called immune reconstitution disease if not stemming from an autoimmune process.\textsuperscript{56} Variations in epidemiologic statistics exist, but early retrospective data showed that about 30% of patients who are at risk of IRIS develop the clinical syndrome. More recent data support a lower incidence overall, about 15%, with higher percentages of almost 38% for patients with CMV retinitis specifically.\textsuperscript{61} Opportunistic infections that have not been treated may reactivate, causing an exacerbation of clinical symptoms. Cytomegalovirus retinitis, tuberculosis, Mycobacterium avium complex, Pneumocystis jiroveci pneumonia, cryptococcosis, progressive multifocal leukoencephalopathy, and herpes zoster infection represent most of the causative opportunistic infections outlined by Walker and colleagues detailing HIV-associated IRIS specifically. Previously undiagnosed infection is termed unmasking, and exacerbation or recurrence of symptoms is termed paradoxical worsening.\textsuperscript{62}

Risk factors for IRIS consist of a lower CD4 count (less than 100 cells/mm\textsuperscript{3}), high viral load, and suboptimal treatment of opportunistic infections before initiating HAART.\textsuperscript{63} Immune reconstitution, which may occur days to months after HAART, is accompanied by an increase in CD4 cells. The pathophysiology of the response is not clearly defined and cannot completely be explained by this increase. Cytokines as well as innate and adaptive immune responses, together with the host immune functional capacity, have been proposed as important factors. Patients may have symptoms of inflammation—specifically, fever, malaise, and lymphadenitis. If an opportunistic infection was not previously treated, the symptoms specific to this infection may present.\textsuperscript{64} Shel-bourne et al. performed a retrospective chart review of patients with HIV infection with Mycobacterium tuberculosis, M. avium complex, or Cryptococcus neoformans and evaluated risk factors for IRIS.\textsuperscript{65} When the opportunistic infection was diagnosed, affected
patients were more likely to have started HAART close to diagnosis, to have been antiretroviral naive, and to have had a more rapid initial fall in HIV-1 RNA levels in response to HAART. Cytomegalovirus retinitis–associated IRIS has sight-threatening implications; therefore, patients with HIV infection having a history of CMV retinitis should have a dilated ophthalmologic examination every 3 months for the first year after initiation of ARV therapy or if visual acuity changes or floaters develop. Wiselz and colleagues detail three case reports of acute respiratory failure after introducing HAART to patients with severe P. jiroveci pneumonia. In the ICU, this clinical picture may present as a therapeutic challenge. Reintroducing steroids or suspending HAART was necessary for these patients to recover.65

In all cases, appropriate diagnostics must be performed to identify whether an opportunistic infection has activated. If identified, the opportunistic infection must be treated appropriately. Overall, symptomatic treatment is the mainstay of therapy. If the IRIS is severe, steroids may be administered for 1–2 weeks and tapered to discontinuation. Doses have not been standardized; however, some experts recommend 1–2 mg/kg of prednisone daily. For mild IRIS, nonsteroidal anti-inflammatory agents can be used for fever and inflammation; if pulmonary inflammation presents, inhaled steroids are therapeutic options. In general, a delay in, or holding of, antiretroviral therapy is not currently recommended because of the life-saving nature of the therapy.66 However, if life-threatening symptoms occur or if permanent sequelae may result, HAART should be deferred. Dheda and colleagues evaluated patients coinfected with tuberculosis and HIV and concluded that initiating HAART reduced immediate and long-term risk of death and AIDS-defining illnesses.67 In addition, patients with a CD4+ cell count less than 100 cells/mm³ are at higher risk of death or new AIDS-defining illnesses during the early phase of tuberculosis treatment and more prone to immune reconstitution. Treating opportunistic infections before HAART will assist in preventing IRIS and decreasing bacterial burden.7,30,67

Patients with long-standing HIV infection are often admitted to the ICU for noninfectious causes.45 It is imperative to consider reinitiating
antiretroviral therapy as soon as clinically feasible. Failure to reinstitute antiretroviral therapy may lead to an iatrogenic nonadherence. Antiretroviral errors are very common in the hospitalized setting and may occur in up to 70% of inpatients. Antiretroviral errors are very common in the hospitalized setting and may occur in up to 70% of inpatients. In the ICU specifically, high rates of acute kidney injury and use of acid-suppressing agents may lead to dosing errors and drug-drug interactions, respectively. In addition, knowledge of crushable administration is important in the ICU, and maintaining available formulations of solutions and suspensions will help ensure the continuity of antiretroviral therapy.

RESPIRATORY VIRUSES

Viral infections may play a prominent role in respiratory disease in the ICU, both community acquired and less commonly through nosocomial acquisition. Community-acquired viruses such as influenza, specifically H1N1, have resulted in significant acute respiratory diseases prompting ICU admission (Table 17.3). This is more likely to occur in the older adult or immunocompromised population and is often associated with community outbreaks. Reactivation of endogenous viruses including HSV and CMV can also occur in immunocompromised patients. Histologic assessment and open lung biopsy of previously healthy intubated patients with suspected ventilator-associated pneumonia have revealed that almost 30% had findings compatible with CMV lung disease, whereas only 3% had HSV. Patients with documented CMV infections have had increased duration of mechanical ventilation and longer ICU and overall hospital length of stay; these infections were inconsistently associated with increased mortality. In addition, these patients had higher rates of bacterial and fungal superinfections, which may also be reflected in the immunocompromised state of most of these patients. Herpes simplex virus appears less likely to be associated with a true pneumonia or bronchopneumonitis, as opposed to a tracheobronchitis. Patients with HSV often have outcomes similar to those with nonviral infections. If active CMV infection is suspected, management with ganciclovir is appropriate; however, consultation with infectious diseases specialists
is recommended. Preemptive or prophylactic management of viral infections in acute respiratory distress syndrome is limited to a single prospective study of intravenous acyclovir showing no clinical benefit in ventilated patients. Despite the unknown contribution of CMV and HSV as viral pathogens in respiratory disease in the ICU, these patients are susceptible to nosocomial outbreaks of viruses including influenza. Both patients and health care workers may serve as potential vectors. Procalcitonin has been investigated specifically in patients with concurrent influenza to determine the presence or absence of bacterial infection. The available data suggest that in patients with concurrent respiratory viral disease, procalcitonin is helpful to determine the need for antibiotics; however, it should not be used as a stand-alone test. The availability of rapid diagnostics outside conventional antigen testing with influenza and respiratory syncytial virus (RSV) using nucleic acid amplification tests and PCR technologies is becoming more prevalent. Commerically available multiplex testing allows for simultaneous investigation of not only several viruses but also atypical bacteria. Use of multiplex PCR for viral pathogens specifically offers several potential advantages in the ICU population: optimizing treatment with both antibacterials and antivirals, limiting the overuse of antibiotics and the subsequent development of resistance, reducing the need for superfluous diagnostic testing, and allowing for proper isolation. Installing multiplex PCR has shown a reduction in the use of antibiotics, primarily in a hematology-oncology population. Data for use in a medical or surgical ICU are limited to date; however, this is a quickly evolving area of study and development. Several other viral pathogens including RSV, adenovirus, parainfluenza, metapneumovirus, and rhinovirus have been implicated in causing primarily respiratory disease. Although most of these pathogens are typically associated with self-limiting infections, serious, life-threatening disease is not uncommon, especially in children younger 1 year and older adults, often with accompanying immunocompromise. Management of these viruses is primarily symptomatic care, and identification by PCR, including commercially available multiplex PCR, is increasingly common for high-volume institutions. The clinical relevance of identifying these
pathogens in the presence of respiratory disease remains debatable, although a growing body of evidence supports their causality of lower respiratory tract infections in immunocompromised adults. Viruses, including virulent strains of coronavirus (CoV) and enterovirus, although naturally common, have been associated with severe outbreaks globally and in the United States, respectively.

**Influenza**

Influenza types A and B are known to cause serious infection in humans and are typically associated with seasonal outbreaks, typically peaking in the winter months. Unlike influenza B, influenza A can be further subtyped by the surface proteins hemagglutinin and neuraminidase. There are 18 different hemagglutinin (H1–H18) and 11 different neuraminidase (N1–N11) subtypes. Viruses are named in accordance with the internationally accepted World Health Organization (WHO) nomenclature originally published in 1980. Each year, 5%–20% of the U.S. population will be infected with influenza, resulting in more than 200,000 hospitalizations. Most of these hospitalizations do not result in critical illness except in patients of extreme age or with immunocompromise. However, since 2009, with the emergence of the endemic H1N1 (an influenza type A) strain, young and middle-aged adults have more commonly been admitted to the ICU with severe acute respiratory distress syndrome. This may be because of the relatively lower immunization rate in this population (less than 50% nationally) and the prior immunity acquired in older patients from exposure to antigenic similar strains. This 2009 strain has now replaced the previously circulating H1N1 virus in humans. The annual deaths associated with influenza range from 3,000 to up to 35,000 annually, and most recently, most are associated with the H1N1 strain. Patients with obesity (body mass index greater than 30 kg/m²) and pregnant women are among the higher-risk populations for critical illness with influenza infection. Proinflammatory cytokines occur at a high rate in the lungs of influenza-positive patients and are responsible for much of the significant morbidity associated with the disease.
Rapid diagnosis is important because many patients will deteriorate 4–5 days after onset of illness, which is associated with typical flu-like symptoms including fever, fatigue, cough, rhinorhea, and myalgias. The historic gold standard for influenza diagnosis is viral cell culture, delays in diagnosis and required laboratory resources make this impractical for routine patient diagnosis, especially during influenza season. The use of rapid diagnostics, specifically molecular-based PCR testing, is recommended for hospitalized patients. Reverse-transcriptase PCR testing is available in both single and multiplex design. Table 17.4 lists commonly available testing methods. The sensitivity of rapid diagnostic tests is typically 50%–70% but ranges from 10% to 80%, depending on the viral replication and specimen collection, storage, and transport. Testing within 3–4 days of onset of influenza infection is more likely to yield positive test results. Specificity is quite high (more than 95%), and false positives are unlikely. A false positive may be achieved if a patient has received the live attenuated virus vaccine within 7 days and an upper respiratory tract sample is used. In addition, if a patient tests positive to both influenza A and influenza B, the unlikely result of having both viruses simultaneously should prompt additional testing at a reference laboratory. False negatives are more common during peak season, and of importance, a negative test should not preclude targeted antiviral
therapy during peak season and in the setting of high pretest probability. In an outbreak, testing several patients will significantly increase the sensitivity.\textsuperscript{83}

On deterioration, patients will develop hypoxemia, shock, and multiorgan dysfunction. Careful monitoring of hemodynamics is required for prompt and timely intubation. Patients may also present with concomitant bacterial pneumonia, especially Staphylococcus aureus, including methicillin-resistant S. aureus, Streptococcus pneumoniae, or Streptococcus pyogenes.\textsuperscript{85} The acute respiratory distress syndrome associated with influenza requires low-tidal volume lung-protective ventilation and an open-lung approach with increased positive end-expiratory pressure. Appropriate fluid management is also essential to recovery. Many patients may not respond to conventional management and may require advanced care to include extracorporeal membrane oxygenation, neuromuscular blockade, nitric oxide, and lung recruitment maneuvers.\textsuperscript{7} Outcomes with these interventions are inconsistent and should be considered on a patient-specific basis.

\begin{table}[h]

\end{tabular}
\caption{Commonly Available Influenza Diagnostic Testing Methods\textsuperscript{83}}
\end{table}

ET = endotracheal; NP = nasopharyngeal.
Antiviral therapy is recommended for all hospitalized patients with influenza.\textsuperscript{78} Neuraminidase inhibitors, including oseltamivir, zanamavir, and most recently peramivir, are recommended for both influenza A and influenza B.\textsuperscript{78,86,87} Oral oseltamivir is recommended by the CDC as first-line therapy for hospitalized, critically ill patients. Zanamavir is available as inhaled version and may be difficult to administer in critically ill patients, especially if intubated. Zanamavir is also contraindicated in patients with underlying respiratory disease such as asthma or chronic obstructive pulmonary disease.\textsuperscript{86,88} Intravenous zanamavir is currently under investigation and available on limited access.\textsuperscript{78} Oseltamivir is orally administered as a prodrug that is rapidly converted to the active form. Oral bioavailability is high and reaches peak concentrations within 1 hour of administration. Standard dosing (75 mg twice daily) for a minimum of 5 days is recommended (Table 17.2), although longer durations should be considered in critically ill patients, depending on clinical response.\textsuperscript{78,86,88} Higher doses of 150 mg twice daily have also been suggested in critically ill patients, although limited data suggest that serum concentrations are adequate with conventional dosing.\textsuperscript{89} Limited pharmacokinetic studies in morbid obesity and pregnancy also suggest that standard doses provide adequate concentrations, despite some clinician practices to increase the dosing to 150 mg.\textsuperscript{90} In critically ill patients, oseltamivir administered by oro- or nasogastric tube was well absorbed, including in those on continuous renal replacement therapy and extracorporeal membrane oxygenation.\textsuperscript{90-92} If absorption is questioned or oral access is not established, intravenous peramivir is recommended.\textsuperscript{78,87} Although intravenous peramivir compared with standard of care had no clinical benefit in hospitalized patients during clinical trials, it was well tolerated.\textsuperscript{87} Treatment should be 600 mg daily for at least 5 days.\textsuperscript{78} A small subset of patients with influenza A may have resistance to oseltamivir. Zanamavir often maintains activity against oseltamivir-
resistant strains, and its use should be strongly considered.\textsuperscript{54,88}

Despite the recommendations and widespread use of the neuraminidase inhibitors for influenza, there are questions regarding their effectiveness. In a 2014 Cochrane review, data from 46 clinical trials showed a modest 14.4- to 16.8-hour reduction in time to first symptom alleviation for oseltamivir and zanamivir.\textsuperscript{93} However, complications of influenza were not carefully examined in most studies, and lack of consistent definitions did not allow for full assessment if a reduction occurred in these influenza-related complications including pneumonia. Prophylactic oseltamivir appeared to reduce symptomatic influenza but did not reduce hospitalizations.\textsuperscript{93} Despite the relative lack of effectiveness shown and general lack of good outcomes data in hospitalized patients, our treatments are limited to aggressive antiviral therapies and supportive care. Ultimate recovery is variable and dependent on the total care of the patient beyond antiviral therapies. Prevention is likely to be the best mode of treatment for most patients. Patients with influenza are more susceptible to bacterial pathogens, as mentioned previously. Postinfluenza S. aureus, including methicillin-resistant S. aureus (MRSA), pneumonia is often common.\textsuperscript{94} In patients with a recent history of influenza infection or severe viral pneumonia, MRSA pneumonia should be considered in the differential and may direct empiric therapy, even in community-acquired infections.

Prevention through vaccination is primarily the responsibility of health care workers, including pharmacists. Many hospitals have introduced mandated vaccine protocols for workers with direct patient care responsibilities.\textsuperscript{95} Despite the limitations in viral coverage associated with the recent available vaccine therapy, use has been shown to reduce influenza infections and prevent health care worker-to-patient transfer and thus the potential for associated outbreaks.

**Respiratory Syncytial Virus**

Respiratory syncytial virus is an RNA virus in the Pneumovirus genus that is responsible for more than 50,000 hospitalizations each year in children younger than 5 years.\textsuperscript{96} An additional 175,000 hospitalizations
with almost 15,000 deaths in adults older than 65 years are reported in the United States. Infants younger than 1 year are at highest risk. By age 3, virtually all children have been infected. Respiratory syncytial virus is a seasonal virus peaking between October and May in the United States. Respiratory syncytial virus may be responsible for up to 2% of nursing home deaths in older adults. The disease manifestations range from common cold symptoms to severe lower respiratory tract disease. The air trapping that results leads to a rapid respiratory rate, a palpable spleen and liver, and typical radiographic findings of hyperinflation and diffuse atelectasis. Bronchiolitis may lead to respiratory failure requiring mechanical ventilation. Around 1%–2% of patients will require admission to the ICU.

Treatment of these patients is primarily supportive care, although many treatments have been studied. Most clinical data remain in pediatric patients. Bronchodilators and corticosteroids have not been shown to improve clinical outcomes and are not currently recommended. Bronchodilators may be used on a trial basis and continued if there is objective improvement. Ribavirin is U.S. Food and Drug Administration (FDA) approved for the management of RSV, despite large controlled studies showing a lack of benefit in clinical end points. The aerosolized form has been used anecdotally with some success and is recommended in pediatric patients with severe, clinical disease and potentially underlying immunocompromise. Administration is continuous or intermittent for 8–24 hours daily for 3–5 days and requires a special device for aerosol delivery (Table 17.2). Ribavirin is also considered a hazardous agent according to the National Institute for Occupational Safety and Health. Precautions during preparation and administration are required. Ribavirin is category X and is contraindicated in pregnancy. Exposure to ribavirin has been seen by health care workers administering the drug, with minor adverse effects including headaches and nausea. Although improvements in delivery continue, pregnant health care workers should be cautioned in delivering the aerosolized drug. On rare occasions, it can worsen bronchospasms for the patient. Palivizumab, a humanized
monoclonal antibody derived from murine samples, and polyclonal immunoglobulins have been used in adults and children with mixed results in a treatment modality.\textsuperscript{102}

Palivizumab is FDA approved for the prophylaxis of RSV in high-risk pediatric patients. The American Academy of Pediatrics updates recommendations on the basis of additional evidence.\textsuperscript{102} The most recent update in the summer of 2014 included premature infants (younger than 29 weeks) who are younger than 12 months at the start of the RSV season, especially those with congenital heart or lung disease.

**Coronavirus**

Coronavirus infections are caused by one of six serotypes, four of which are extremely common, and most adults have been infected with one or more during their lifetime.\textsuperscript{103,104} Typically, these are responsible for mild, self-limiting upper respiratory tract diseases. Two strains in particular, SARS-CoV and MERS-CoV, are responsible for global outbreaks of severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), respectively.\textsuperscript{94} In 2002, an outbreak of SARS, which began in China, was responsible for almost 8,100 infections and more than 750 deaths. Since 2004, however, there have been no documented cases of SARS worldwide.\textsuperscript{94,105} The SARS-CoV strain disproportionally infects adults and carries a case fatality rate of almost 10%.\textsuperscript{5} Most patients present with 5–7 days of fever, dyspnea, cough, malaise, and other generalized respiratory symptoms. About 25% will have diarrhea, and of concern, 20% will develop severe respiratory distress requiring mechanical ventilation. Transmission occurs from human-to-human contact and peaks during the second week of illness (day 10) concurrently with peaks in viral load. Management is primarily symptomatic care, although several agents have been studied in humans.\textsuperscript{5,106} Ribavirin, interferon, and lopinavir/ritonavir have all shown antiviral activity in vitro.\textsuperscript{103,107} Clinical studies, however, do not support the routine use of these agents. Corticosteroids and intravenous immunoglobulin (IVIG) also failed to
show improved outcomes.\textsuperscript{5,103} Patients who received ribavirin or corticosteroids also had higher rates of significant adverse drug events, and those who received pulse-dose methylprednisolone specifically had higher rates of 30-day mortality, which should be considered before administration.\textsuperscript{5} Proper isolation and infection control measures are essential to prevent patient-to-health care worker or patient-to-patient transmission in an institutional setting.

The MERS-CoV strain was responsible for a recent outbreak, which began in 2012 in Jordan. Since then, as of June 2015, about 1,200 cases have been reported to WHO.\textsuperscript{107} Outside the Middle East, where most cases have been reported, South Korea has also had a significant outbreak of almost 200 cases. Only two cases have been reported in the United States, both from international travelers from the Middle East.\textsuperscript{108} Like with SARS-CoV, bats are thought to be the primary vector of infection.\textsuperscript{109} However, unlike with SARS-CoV, human-to-human transmission, although possible and documented, appears to be somewhat less of a concern. Adults are primarily affected (in more than 90\% of cases), and the median age is around 50.\textsuperscript{94,109} Most patients with MERS-CoV infection, about 75\%, have had associated comorbidities, and more than 75\% of patients have required hospitalization. Respiratory failure is common, requiring mechanical ventilation. Patients often have laboratory abnormalities including leukopenia, lymphopenia, thrombocytopenia, and elevated lactate dehydrogenase. The case fatality rate appears to be 35\%–45\%.\textsuperscript{94,108,109} Table 17.5 offers a detailed comparison of SARS-CoV and MERS-CoV. Early recognition and diagnosis remains difficult in patients with MERS infection. The primary method of diagnosis is MERS-CoV PCR testing and is available on respiratory, blood, and stool samples. There are reports of false negatives, especially on inadequate upper respiratory tract samples early in the disease process. Retesting of patients with high pre-test probability may be required at this time.\textsuperscript{109} Most state reference laboratories in the United States are equipped to handle specimen testing; however, contact with the CDC for suspected cases is required. Treatment of these patients is primarily symptomatic care, recognizing the aggressive and virulent
nature of this virus. Interferon, ribavirin, cyclosporine A, and mycophenolic acid have shown effects in vitro; however, none has shown positive clinical outcomes to date.\textsuperscript{106,109} Limited knowledge of the viral kinetics currently limits targeted therapies. Convalescent serum from survivors may be considered in the absence of other proven therapies.\textsuperscript{106,107}

Enterovirus

In 2014, a nationwide outbreak of enterovirus infection occurred in the United States, infecting almost 1,200 people, primarily infants and young children. This population is primarily affected because of the lack of natural immunity acquired from exposure to related viruses. The virus strain in this particular outbreak of severe disease, enterovirus D68 (EV-D68), is only one of almost 100 identified non-polio enteroviruses. Patients present with severe hypoxemia, wheezing, and difficulty breathing. Many of these patients have underlying asthma (75%). Very few (about 25%) patients have fever on initial presentation. Consideration of enterovirus diagnosis is important to prevent human-to-human transmission, which may occur through droplets. Management of underlying lung disease and acute respiratory decline is essential, which may often include corticosteroids. There is no conclusive evidence of the effectiveness of pharmacologic interventions, aside from symptomatic care of acute respiratory syndrome. The death rate appears to be about 1%. During the 2014 outbreak, about 100 patients were also given a diagnosis of an acute flaccid myelitis, first reported in Colorado. Although it has not been conclusively proven, evidence suggests and experts agree that this is a unique presentation of EV-D68. Many of these patients have remained symptomatic, and only a small percentage of patients have fully recovered. Therapeutic interventions including corticosteroids, IVIG,
and convalescent serum have been tried, but no evidence supports their benefit at this time.\cite{110,112}

## VIRAL HEMORRHAGIC FEVERS

Viral hemorrhagic fevers represent a group of viruses from four distinct families: arenaviruses, filoviruses, bunyaviruses, and flaviviruses. All are RNA viruses enveloped in a lipid bilayer that require an animal or insect as the vector. Outbreaks of these infections are primarily relegated to the geographic areas where the natural hosts live.\cite{22} However, in the example of Marburg virus, the first reported cases in 1978 were in Marburg and Frankfurt, Germany, and Yugoslavia secondary to exposure to infected monkeys from the host region.\cite{113} Transmission may occur from human-to-human contact for some VHFs, including Ebola, Marburg, and Lassa. Recent outbreaks of Ebola virus disease in 2014 that affected the United States and other Western countries have increased the sensitivity and need for preparedness for VHFs.\cite{22,61} Global transportation has brought the world much closer, shrinking once-distinct geographic regions for disease.

Patients often present with typical, generalized viral illness symptoms including fatigue, fever, weakness, and muscle aches. Severe disease is associated with bleeding, although this is not necessarily present in most patients, and patients often die secondary to severe hypovolemia and multiorgan failure. Treatment is primarily symptomatic care, although emerging antiviral and convalescent serum therapies are under development or have some limited experimental data. Ribavirin has been used effectively in patients with Lassa fever and hemorrhagic fever renal syndrome.\cite{114} The CDC has developed practical, institutional guidelines for managing and preventing VHFs.\cite{61} Guidelines are often updated on the emergence of new outbreaks and availability of new data. Understanding and management of these infections is limited in part because of the relative youth in discovery of many of these VHFs as well as because much of the burden of disease has been isolated to the developing world in Sub-Saharan Africa. Ebola virus disease, highlighted in detail in the following text, can serve as an
example in management and prevention for other VHFs.

Ebola virus, a member of the flavivirus family, was first identified in 1976 near the Ebola River in the present-day Democratic Republic of the Congo. Although a vector has not been fully confirmed, many experts agree that the fruit bat is the most likely host. The virus affects both humans and primates. Several outbreaks have been reported historically, localized primarily to Central Africa and the eastern coastline. The most recent outbreak, which began in March 2014 in Guinea, has resulted in almost 28,000 infected individuals and more than 11,000 deaths.\textsuperscript{115} In June 2015, at least several small pockets of disease remain in Sierra Leone. The incubation period can be as short as 2 days and as long as 3 weeks; however, the average onset of symptoms is typically 8–10 days from infection.\textsuperscript{115} Transmission can be directly from the infected primate or the vector or between humans through contact with infected body fluids including blood, sweat, urine, and saliva. Viral RNA typically peaks 3–5 days after infection and is higher among fatal cases than among survivors.

Like with many other VHFs, patients often present with generalized symptoms including fever, fatigue, malaise, generalized weakness, hiccups, and muscle aches.\textsuperscript{22,116,117} Gastrointestinal symptoms typically appear in the first 5 days and are common. Diarrhea is very severe, with volumetric losses mimicking those of severe cholera. Severe hypovolemia preempting additional sequelae (e.g., acute kidney injury) is often the primary reason for ICU admission. Despite volume losses of up to 10 L/day, patients have increased body weights of 15–20 kg because of extreme third spacing. Electrolyte abnormalities including hyponatremia, hypokalemia, and hypocalcemia are severe and require prompt attention. In severe cases, patients have multiorgan failure and other effects including seizures and arrhythmias.\textsuperscript{22,116,118}

Prompt diagnosis, followed by isolation, is the first and most important intervention to prevent further exposure and limit spread of disease. Diagnosis is based initially on appropriate travel history and corresponding symptoms. Ebola PCR testing is available but, because it is not routinely available in institutions, requires a delay for send-out testing at a reference laboratory.\textsuperscript{22,61,119} Rapid diagnostic testing is not
currently commercially available but is under investigation. To prevent transmission, a level 4 biocontainment facility setup is required. In general, the patient requires 24 hours/day, 7 days/week one-to-one or two-to-one nursing care using strict isolation and appropriate personal protection equipment (PPE).\textsuperscript{22,61} Staff must be specially trained on the donning and doffing of PPE. Laboratory specimens for testing require point-of-care testing or designated equipment in a centralized laboratory. Although medication transfer and administration are managed by the nurse, medication safety checks and balances such as bar scanning should be maintained, whenever possible. The CDC outlines the appropriate development of a biocontainment team and isolation ward.\textsuperscript{61}

Treatment of these patients is primarily symptomatic care because no antiviral agents have shown effectiveness on a large scale. Some experts recommend the use of lactated Ringer solution (20 mL/kg) boluses with aggressive intravenous electrolyte replacement.\textsuperscript{22,118} Sequelae such as disseminated intravascular coagulation, hypotension, arrhythmias, and/or seizures should be managed like in other critically ill patients. Antibiotics are not indicated unless a secondary bacterial infection develops.\textsuperscript{22,118} Experimental antivirals have been used with success, and several are currently under development. Without controlled trials, little is currently known about the safety and effectiveness of these antivirals in humans. Convalescent serum from survivors has also been used with success.\textsuperscript{120} Antibodies that develop to Ebola virus disease are thought to remain for about 10 years.\textsuperscript{62} At least one reinfection case has been documented.\textsuperscript{115}

\section*{ARBOVIRUSES}

Arboviruses represent a broad group of viruses with arthropod vectors, most commonly mosquitoes and ticks. The most common arboviruses and their characteristics are listed in Table 17.6.\textsuperscript{1,121,122} Knowledge and discovery of these viruses varies significantly because the first reports of Dengue fever date to AD 992 in the Encyclopedia of Chinese Medicine.\textsuperscript{123} West Nile virus (WNV) was first identified in 1937, since
being recognized in the United States at the turn of the 20th century. Throughout history, these viruses have caused sporadic epidemics globally, but rarely have they caused a significant burden of disease in the United States. Globalization with enhanced international travel during the past 3–4 decades has increased the spread of the disease and emergence in new parts of the world. The incubation period ranges from 2 days to 2 weeks in most patients. Many infected patients have self-limiting disease; however, severe infections requiring hospitalization result in a subset of patients. Symptoms range from general “flu-like” illness to severe respiratory distress, multiorgan failure, and shock. Symptomatic care is the hallmark of treatment with no active antiviral therapies available. In some instances, IVIG has been used on a limited basis with mixed results. In a pediatric population in Nepal with Japanese encephalitis, IVIG at 400 mg/kg/day for 5 days resulted in higher antibodies and interleukin (IL)-4 and IL-6 levels in treated patients than in those receiving standard of care. Clinical outcomes, however, remained the same in both groups. Sporadic case reports show mixed results on the effectiveness in WNV encephalitis. Immunoglobulin lots obtained from endemic areas are likely to have higher viral titers specific to many of these viral infections and potentially enhanced effects. In viral encephalitis, some experts suggest using intrathecal or intraventricular administration to enhance antibody exposure across the blood-CSF barrier. Although IVIG may be considered in many of the flavivirus infections with progression despite aggressive symptomatic care, caution should be used with untoward effects. The optimal dosing and route of administration for a suspected CNS infection are unknown.

## Dengue Fever

Dengue fever is the most common arbovirus infection, only behind malaria for infection-related sequelae in the tropics. The mosquito in the genus Aedes is the primary vector, and human-to-human transfer of disease is not confirmed. Infection occurs with one of four serotypes, DEN 1–4, and infection with one serotype does not offer protection against the others. Subsequent infections, in fact, with different
serotypes may increase the severity of disease and the likelihood of associated hemorrhagic fever or shock. The infection rate worldwide has increased 30-fold in the past 50 years. Dengue fever worldwide is primarily a disease of infants and children, although disease in a returning traveler from an area where Dengue fever is endemic may occur in adults as well. Diagnosis is based on travel history, together with fever and two of the following criteria: nausea/vomiting, rash, aches and pains, positive tourniquet test, leukopenia, or one of the warning signs for severe disease. Viral serologies are also available for Dengue, which are often used for confirmation. The hemagglutination inhibition assay and the IgG and IgM enzyme immunoassays are available, with the IgM enzyme immunoassay test being the most commonly used. Rapid PCR testing is also available that can diagnose the disease early in the infection window (less than 48 hours), but it requires a reference laboratory for most institutions. Dengue infection occurs in three distinct phases over an average 10-day period: febrile, critical, and recovery. The hallmark of the clinical course is an increase in capillary permeability and a resultant plasma leakage and increase in hematocrit. Plasma leakage peaks over a 24- to 48-hour period during the critical phase. This is accompanied by a significant decrease in white blood cell and platelet counts. The severity of the plasma leakage may lead to other sequelae including shock and multiorgan failure, although this is rare. Other laboratory abnormalities seen in the critical phase include hypoalbuminemia, elevated liver enzymes, thrombocytopenia and leukopenia, and abnormal coagulation profile.

Management of severe Dengue fever is primarily symptomatic care and focused on appropriate fluid balance. Repeated boluses may be needed in severe plasma leak; however, maintenance fluids should be carefully balanced and adjusted according to patient requirement. Further management of resultant hypotension beyond intravenous fluids may be required in rare situations. Electrolyte shifts are also common. Antibiotics are not indicated unless a secondary bacterial infection occurs. The mortality rate is less than 1%, and many patients can be treated as outpatients, with proper education and knowledge of
immune status. Prevention is a primary focus with the lack of anti-viral therapies. Avoiding mosquito acquisition is the best current strategy. Vaccine development is under investigation, although no timeline is available.\textsuperscript{1,123}

**Other Zoonotic Infections**

The rabies virus is an RNA virus transmitted through the saliva of an infected animal vector. In the United States, bats, raccoons, skunks, and foxes are the primary sources of infection, depending on the geographic region. Each year in the United States, about 6,000 animals, 92\% of which are nondomestic, and two or three humans are infected with rabies. Worldwide, however, almost 75,000 cases occur annually.\textsuperscript{127} The case fatality rate is 100\%, and only three survivors who have not received postexposure prophylaxis with immunoglobulin or the rabies vaccine have been reported.\textsuperscript{128} After exposure to an infected animal, the average incubation period is 20–90 days, although time to presentation is quite variable.\textsuperscript{41,129} Patients often have localized symptoms after the initial bite has healed, including localized pain, numbness, tingling, and paresthesias together with generalized viral syndrome of fatigue, malaise, and fever. The two distinct forms of rabies are encephalitic in 80\% of patients and paralytic in 20\% of patients. It is not clearly understood why and how each may manifest. The encephalitic form has a greater burden of disease involving the spinal cord and peripheral nerves. Patients have episodes of hyperexcitability separated by lucid periods. Autonomic dysfunction is common. The hallmark feature is hydrophobia, which involves diaphragmatic spasms lasting 5–15 seconds on attempts to swallow. This can also be triggered by the sight of liquids and draft of air. Patients quickly progress to coma and multiorgan failure. Paralytic rabies typically begins at the bite location with spread to quadriparesis and bilateral facial weakness. Hydrophobia does not typically occur in this form of rabies, although progression to coma and organ failure is imminent but often delayed compared with progression with the encephalitic form.\textsuperscript{41,130}
Early presentation after a bite but before the onset of symptoms will trigger a proactive response to determine the necessary prophylaxis. Animal testing can be done quickly using direct fluorescent antibody testing on the brain tissue. If it is determined that a high-risk exposure has occurred, the previously unvaccinated patient will receive a single dose of human rabies immunoglobulin (HRIG) infiltrated into the wound and surrounding areas.128,129 Patients will also receive a four-dose series of rabies vaccine, with the first dose beginning the same day and subsequent doses given on days 3, 7, and 14. The vaccine should be administered intramuscularly in the deltoid area at a site distant from the HRIG. If the entire volume of the HRIG cannot be administered local to the bite, the remaining volume can be administered intramuscularly at a site distant from the vaccine. This is to reduce the potential inactivation of the rabies vaccine. Patients who were previously vaccinated should receive two doses of the vaccine, but HRIG is not indicated.128

Among the three survivors known to date who did not receive postexposure prophylaxis, a 15-year-old girl who survived was placed in a therapeutic coma with intravenous midazolam and supplemental phenobarbital for a burst-suppression pattern on EEG. In addition, she was maintained on continuous infusion ketamine and provided antiviral therapy with ribavirin and amantadine. This protocol, based on very limited evidence, has been labeled the “Milwaukee protocol.”128,131 Despite success in this patient, at least 20 failures have been documented using a similar approach since its publication.132 Although these agents are under investigation, no evidence currently suggests that this pharmacologic approach promotes clearance of rabies or resolution of symptoms.

**SUMMARY**

Pharmacists contribute daily to improving patient care in the ICU through improving medication safety, promoting evidence-based practice, optimizing medication delivery, and reducing unnecessary costs. For many critical care pharmacists, managing infectious
diseases is a primary function of day-to-day patient care activities. Viral infections play a critical role in the burden of infectious diseases in the ICU. Although many of these are acquired in the community, the risk of nosocomial viral infections is increasingly prevalent. Pharmacists should always practice and promote appropriate infection control measures, abiding by institutional guidelines. Good hand hygiene is a simple but proven effective measure for reducing the transmission of nosocomial pathogens from health care workers to patients or between patients. The continued development of rapid diagnostics and the availability of new testing platforms for viral pathogens such as multiplex PCR provide an additional, integral role for pharmacists. Knowledge and interpretation of such tests are important for properly managing unnecessary antibiotics, discussing the potential need for targeted antiviral therapy, or communicating the need for infection control measures. Supportive care is the cornerstone of management for many invasive viral infections; however, some of the more prevalent viral infections in the ICU have proven, available, evidence-based, antiviral therapies. For antivirals, which are usually much less commonly used than antibacterials, knowledge of appropriate dosing, administration, and adverse effects is limited to a select few members of the treatment team. Many of these patients will also have accompanying immunocompromised states, requiring a working knowledge of immunomodulators and immunodeficiencies. Research is significantly lacking in the management of many invasive viral infections, priming pharmacists for an opportunity to help lead efforts to enhance the clinical investigation of these patients.

LEARNING OBJECTIVES

1. Determine the correct use of antibiotics during surgical prophylaxis pertaining to indication, dose, duration, and timing.

2. Identify risk factors for surgical site infections (SSIs) and the unique risks faced by critically ill patients.

3. Identify differences in the causative pathogens for SSIs among intensive care unit (ICU) patients.

4. Synthesize an antibiotic prophylactic approach for the ICU patient receiving antibiotics for a concomitant infection.

5. Describe which procedures performed at the ICU bedside warrant antibiotic prophylaxis and the preferred regimen.

INTRODUCTION: BASICS OF SURGICAL PROPHYLAXIS

Surgical site infections (SSIs) precipitate a cascade of events that often result in significant morbidity, increased mortality, and substantial costs to health care systems and patients. Prevention of these SSIs is fundamental to clinical practice whether the patient originates in the intensive care unit (ICU), hospital ward, skilled nursing facility, or is admitted from home. Antimicrobial prophylaxis plays an important role in the prevention of infections, but their administration is only one step in a comprehensive infection prevention program. Basic infection control practices are the core of preventing SSIs and should include
controllable factors such as targeted temperature control, blood glucose control, hair clipping versus shaving, venous thromboembolism prophylaxis, and perioperative β-blocker administration. Equally important are controllable factors of antimicrobial administration that include which surgical cases may benefit antibiotic selection, antibiotic dosing, timely administration before surgical incision, and duration of postoperative prophylaxis. Pharmacists have been involved in collaborative improvement efforts on the national, state, local, and institutional level to improve antimicrobial use during the perioperative period. Major national initiatives developed by the Centers for Medicare & Medicaid Services (CMS), including the Surgical Care Improvement Project and Physician Quality Reporting System (PQRS), have resulted in dramatic improvements in standardizing antimicrobial administration and infectious control practices centered on the surgical procedure. For example, CMS requires collection and reporting of administration of antibiotic prophylaxis through the PQRS, which is shown electronically on public access websites to allow the consumer to compare performance among hospitals on specific surgical procedures.

Many questions remain unanswered with perioperative antimicrobial prophylaxis. An area that is largely absent in recommendations from CMS and SSI prevention guidelines is the decision-making process for patients receiving antibiotics for other infections, including patients residing in the ICU. The pharmacist and surgeon are often left without guidance regarding the correct approach to antimicrobial prophylaxis among these patients. Very few answers to these questions are found in the literature; however, a basic understanding of antimicrobial prophylaxis and the targeted organisms that cause these infections provides evidence for best practices. These are important considerations for patient safety, potential antimicrobial resistance, burden of antimicrobial use, and ties to CMS reimbursement policies. This chapter will examine the fundamentals of antimicrobial surgical prophylaxis, review surgical procedures in the ICU and surgical suite, and address antibiotic administration in patients receiving active treatment for infection.
Principles of Prophylaxis

Surgical Site Infections

The National Healthcare Safety Network has defined the criteria for determining an SSI. Infections can be classified in three categories: superficial incisional site SSI, deep incisional SSI, and organ space SSI.\textsuperscript{1,2} Superficial infections usually occur within 30 days of the operative procedure and involve the skin and/or surrounding subcutaneous tissue of the incision site plus the clinical findings of purulent wound drainage, aseptically isolated organisms from the wound, and at least one sign of infection: pain or tenderness, or localized swelling, redness, or heat. Additionally, any culture positive or noncultured superficial incision that is deliberately opened by or determined by a surgeon or another clinician as an incisional SSI, is classified as a superficial infection. Deep incisional infections also occur within 30 days, or if an implant is left in place, the period is extended to 1 year, and the SSI appears related to the procedure. Deep tissue infections involve the fascial and muscle layer and/or deep soft tissue. An SSI is confirmed if the surgical site has purulent drainage or the incision spontaneously dehisces or is opened by the surgeon and is culture positive. If not cultured, the patient must have other signs of infection that include fever (temperature greater than 38°C), localized pain or tenderness, abscess, or other evidence of infection found on examination or during reoperation, histopathologic or radiologic evidence, or visual diagnosis by the clinician. Organ space SSIs may occur in a part of the body excluding infections isolated to superficial or deep tissues (e.g., those of the skin incision, fascia, or layers of muscle) and is more likely to result in systemic culture of infecting pathogens. Organ space infections follow the same 30-day and 1-year criteria of deep incisional SSIs and meet the criteria of purulent drainage from a drain placed through the wound, organism isolated aseptically, abscess or radiologic or histopathologic evidence, or direct examination with evidence of infection. Complete descriptions of these criteria are found elsewhere.\textsuperscript{3}
Surgical Site Pathogens

Common pathogens associated with SSIs are usually associated with skin flora that include Staphylococcus aureus and coagulase-negative organisms such as Staphylococcus epidermidis. In procedures that penetrate areas harboring other pathogens (e.g., intra-abdominal, colon), the pathogens associated with SSI also include Enterococcus sp., enteric gram-negative rods (e.g., Escherichia coli, Proteus sp.), and anaerobes (e.g., Bacteroides sp.). There is an increasing understanding of pathogen access to the surgical wound by hematogenous spread, through drains, or through slow-healing wounds. In addition to preoperative risk factors, postoperative factors that have been associated with SSIs may include prolonged hospital stay or ICU admission, admission from a long-term care facility, poor wound healing, anticoagulation, respiratory insufficiency, and prolonged antimicrobial administration beyond the first postoperative 24 hours.

Antimicrobial Resistance

Antibiotic resistance is an increasing cause of SSIs that has led to increased morbidity and mortality and associated costs of care for these complicated infections. The incidence of methicillin-resistant S. aureus (MRSA) and S. epidermidis has gradually risen and is now a major cause of SSIs in some health centers. Awad and colleagues showed a greater than 45% rise in MRSA isolates from 288 surgical cases requiring surgical debridement. A comparison of SSIs caused by methicillin-sensitive S. aureus (MSSA) and MRSA showed a 90-day postoperative mortality rate of 6.7% versus 20.7% (p<0.001) and a longer length of hospital stay in the MRSA group than in the MSSA group. This study showed that the longer a patient remains in the ICU, the more likely the causative pathogen for the SSI will be multidrug resistant and include not only MRSA but also gram-negative Enterobacteriaceae and vancomycin-resistant Enterococcus sp.

Antibiotic Selection
In general, antibiotic prophylaxis immediately before surgical incision reduces the overall incidence of SSIs. The choice of antibiotics should target the most common pathogens associated with a specific surgical procedure. S. aureus and S. epidermidis are the most common causes of SSI; therefore, a regimen that includes coverage of these pathogens is warranted. Cefazolin, based on its wide availability, low cost, and activity against these common pathogens, is included in most single-agent or multidrug regimens. Surgical procedures and recommended antibiotics are listed in Table 18.1. Because of the changing sensitivity patterns of pathogens, vancomycin has been added to some regimens. The routine use of vancomycin is discouraged because of the risk of indiscriminate use and development of resistance. Each institution must carefully look at its MRSA rates in SSIs and decide the proper use of vancomycin. It has been argued that health care centers with a high incidence of MRSA should routinely use vancomycin, although the definition of “high incidence” has yet to be determined. Because vancomycin has a long half-life, a single dose before surgery is adequate in most patients. In patients allergic to β-lactam antibiotics, either clindamycin or vancomycin is a reasonable alternative guided by the institution resistance patterns. In some surgical procedures (i.e., intra-abdominal), aerobic and anaerobic gram-negative bacteria cause more SSIs, and in these cases, prophylactic coverage should be expanded to antibiotics with activity against these pathogens, such as cefoxitin, cefotetan, or ertapenem. Extended-spectrum agents are generally not recommended for routine antimicrobial prophylaxis because of broad exposure to bacterial flora and the potential for developing resistance.

**Antibiotic Delivery**

Perhaps the most important factor in preventing SSI after selecting the correct antibiotic is the timing of administration in relation to the initial incision. Many would say that the pre-incision timing of the antimicrobial is as important as, if not more important than, the agent selection because a common error in prescribing presurgical antimicrobials is coverage that is too wide. If the dose is given too late, infection can
occur. In a 1961 study, Burke showed that, in an animal model, administration of antibiotics before the incision was more efficacious than administration after incision. These data were confirmed by a landmark prospective human study by Classen and colleagues, which showed that, in 2,847 patients undergoing elective clean or “clean-contaminated” surgical procedures, administration of antibiotics within 2 hours of the initial incision was associated with a significantly lower rate of SSI. Administration before the 2-hour window or after the incision was similar to placebo administration in the incidence of SSIs. More recent data analyses from a hospital largely noncompliant with this recommendation showed a reduction in SSIs from 21.6% to 4% when administered within 30 minutes of the incision. Since the Classen et al. study, investigators have tried to find the optimal delivery time for the antibiotic before incision. Currently, 60 minutes or less is recommended, but this broad recommendation is being questioned. A multicenter study of prophylactic antibiotic administration in 1,922 patients undergoing total hip arthroplasty showed the lowest infection rate among patients receiving antibiotics within 30 minutes of the incision versus 31–60 minutes. Substantially higher infection rates occurred if the prophylactic antibiotic was administered 61–90 or 91–200 minutes before surgery and 0–30 minutes or greater than 30 minutes post-incision. Examination of more than 32,000 cases in a retrospective cohort study of antibiotic surgical prophylaxis showed a small increase in the incidence of SSI if the antibiotics were administered within 15 minutes of the incision. Vancomycin, which requires a minimum 1-g/hour infusion rate, was studied in more than 2,000 patients undergoing coronary artery bypass grafting or valve replacement surgery. The incidence of SSIs coinciding with initiating the vancomycin infusion before the incision was 3.4% (16–60 minutes), 26.7% (0–15 minutes), 7.7% (61–120 minutes), and 6.9% (121–180 minutes). Other studies have found similar results. Thus, the optimal antibiotic administration appears to be 15–60 minutes before the incision, but confirmatory randomized controlled trials are needed to confirm this as the optimal interval.
Duration of Prophylaxis

The number of doses, or the duration of antibiotic delivery post-surgery, has remained controversial. Although several studies have compared short- and long-term administration with the same antibiotic, the shorter duration has not been universally accepted. National data analyses show that postoperative durations are now in compliance with national guidelines for less than 24 hours or less than 48 hours for cardiovascular surgical procedures. National quality measures have forced compliance with these guidelines. The main duration controversies are in patients with indwelling drains, or in patients on antibiotics for a primary infection before the procedure. McDonald conducted a 1998 systematic review of single- versus multidose antimicrobial prophylaxis for major surgery.\textsuperscript{16} Twenty-eight studies were identified that compared the same antibiotic administered as a single dose or as multiple doses. The results showed no difference in SSIs of single versus multiple doses or the length of the dose (greater than 24 hours vs. 24 hours or less) or by the type of surgery. The results showed no clear benefit for prolonged antimicrobial prophylaxis to prevent SSIs. Some surgical procedures may be at greater risk of SSI and require several doses of antibiotics postoperatively. Cefmetazole was compared as a single dose versus three doses (over 24 hours) in colorectal surgery with a resulting SSI rate of 14.2% and 4.3%, respectively.\textsuperscript{17} This is the only study to show that multiple doses are better than a single dose. A Cochrane review of antimicrobial prophylaxis for colorectal surgery suggested a slightly higher, but not statistically significant increase in SSI with single dose versus multiple dose over 24 hours.\textsuperscript{18}

*a* Clindamycin or vancomycin may be administered in β-lactam allergy for gram-positive coverage.

*b* Aztreonam, aminoglycoside, and, occasionally, a fluoroquinolone may be added for additional gram-negative coverage or gram-negative coverage with β-lactam allergy. SSI = surgical site infection.

The authors did not mention whether a second dose of antibiotic was administered intraoperatively in prolonged surgical procedures. However, they did conclude that high-quality evidence showed that antibiotics targeting both aerobic and anaerobic pathogens were more effective. Ertapenem is the only U.S. Food and Drug Administration label-approved antibiotic for single-dose prophylaxis in colorectal
surgical procedures. Few studies have compared a short duration of prophylaxis in cardiovascular surgical procedures. A study of more than 2,800 patients undergoing prolonged cardiovascular surgical procedures compared the SSI rate of 48 hours or less with more than 48 hours of antimicrobial prophylaxis. The results showed no difference in the SSI rate between the two durations; however, with the longer duration, when an infection did occur, it was more likely (odds ratio 1.6% [95% confidence interval, 1.1–2.6]) caused by an antimicrobial-resistant pathogen.  

Repeat Dosing

Antibiotics with short half-lives require repeated dosing in prolonged surgical procedures to ensure adequate tissue concentrations at the surgical site. If the surgery exceeds 2 half-lives of the antibiotic, repeat dosing is necessary. For example, cefazolin with a half-life of 2 hours should be redosed if the time from the start of antibiotic administration and the surgical procedure exceeds 4 hours. Antibiotics with a longer half-life (e.g., ceftriaxone with an 8-hour half-life) generally do not require repeat dosing. With repeated dosing guidance now available, institutions should consider developing additional guidelines for the frequency of intraoperative dosing to avoid excessive under- and overdosing of antimicrobials.

Dose

To achieve adequate tissue concentration preoperatively, the antimicrobial dose should be chosen on the basis of the type of surgery, antibiotic pharmacokinetics, and individual characteristics of the patient. Early studies of antimicrobial prophylaxis used fixed dosing; however, weight-based dosing is increasingly recognized as ensuring adequate drug concentration at the incision site. Standardized fixed doses do have merit because they avoid the common pitfalls of calculations that lead to dosing errors and compromise patient safety. Obesity rates have been rising in the United States, with estimates of more than 66% of adult Americans classified as overweight or obese,
which may affect tissue concentrations of antibiotics at the point of incision.\textsuperscript{19}

The most recent guidelines for surgical prophylaxis recommend intravenous cefazolin 2 g for patients weighing more than 80 kg and 3 g for those weighing more than 120 kg.\textsuperscript{3} However, only a few studies have addressed dosing in the patient with obesity, most of which have been directed toward the patient with morbid obesity undergoing bariatric surgery. Nonetheless, the clinician should be aware of the potential impact of obesity on antimicrobial penetration into fat tissue and to the surgical incision site. The pharmacokinetics of a single dose of cefazolin were examined in 25 patients (body mass index [BMI] range 43.7–55.7 kg/m\textsuperscript{2}) undergoing elective surgical procedures. Patients were divided into four groups according to their BMI and then assigned to receive cefazolin 2 g intravenous push, 2 g by 30-minute infusion (two different groups), and 3 g by 30-minute infusion. Serum cefazolin concentrations were determined in sequential format before surgery through 360 minutes after initiating the infusion. At all BMIs and doses, the cefazolin pharmacokinetics exhibited similar mean concentrations at 30 minutes after the dose and displayed concentrations of 67.1–84.8 mcg/mL and 22.9–40.8 mcg/mL at 120 and 360 minutes post-dose, respectively. The authors concluded that a single 2-g cefazolin dose provided adequate serum concentrations regardless of BMI for surgical procedures of less than 5 hours.\textsuperscript{20} In contrast, 38 patients undergoing Roux-en-Y gastric bypass for morbid obesity were given cefazolin 2 g intravenously followed by a second dose 3 hours later. Patients were assigned to one of three groups according to their BMI (40–49, 50–59, 60 kg/m\textsuperscript{2} or greater). Serum cefazolin concentrations were inadequate in 52%, 68%, and 73%, with therapeutic tissue concentrations achieved in only 48.1%, 28.6%, and 10.2%, respectively.\textsuperscript{21} Pharmacists responsible for dosing antibiotics in surgical prophylaxis should be knowledgeable of pharmacokinetics and pharmacodynamics in applying weight-based dosing, and weight-based dosing, versus standard dosing, should be the new standard of practice. Aminoglycosides and vancomycin are examples of antibiotics used in surgical prophylaxis with the dose based on weight.
Traditionally, a 1-g dose of vancomycin has been administered for surgical prophylaxis. In a study of 216 patients who screened positive for MRSA before elective total joint or spine surgical procedures, a vancomycin 1-g dose was compared with a weight-based dose of 15 mg/kg. A total of 149 patients (69%) were determined to be underdosed, and an additional 22 patients (10%) were overdosed. The predicted vancomycin value was less than 15 mg/L in 60% of patients receiving the 1-g dose.\textsuperscript{22}

Antibiotic dosing should be appropriately adjusted for renal dysfunction. In single-dose administration, the dose usually needs no adjustment for renal impairment; however, multidose regimens may need the dose reduced or the interval extended, depending on the estimated glomerular filtration rate and antibiotic renal clearance.

**ICU Patients**

Many ICU patients receive antibiotics for other infections before their surgical procedure. This scenario often raises the question of whether additional antibiotics are required before the procedure. Unfortunately, there are no randomized trials to guide the clinician in this decision. Rather, the decision must be made considering the antibiotics being used to treat the infection, their antimicrobial coverage, the length of hospital stay, and the most recent dose in proximity to the surgical procedure. If the antibiotics used for the infection are substantially different in coverage from what would be used for surgical prophylaxis, the recommended dose of the antibiotic commonly used in the procedure should be administered at the appropriate time and duration. However, if the antibiotics being used for the existing infection consistently cover the potential pathogens associated with the procedure, a prudent approach would be to adjust the time of administration to coincide with the usual administration of prophylaxis, or if the times are considerably different from what would be required for the procedure, an additional dose may be given within 1 hour before the incision.
ICU Specifics and Risks of SSIs

Many factors, including several comorbidities, depressed host defenses, the presence of invasive devices, prolonged antibiotic courses, immunosuppressive therapy, and exposure to resistant bacteria, make infectious complications in the critically ill population of concern. Specifically, infectious insults in the ICU environment are more common than infectious complications in non-ICU patients, with at least twice the risk of mortality as in patients who are not affected by an infection.\(^{23,24}\) These increases in prevalence and suboptimal outcomes are a result of several variables encountered by critically ill patients.\(^{23,25}\)

Many patients admitted to the ICU have comorbidities or acute syndromes that precipitate an immunocompromised state. This transient state of depressed immune function predisposes critically ill patients to infection. Even previous immunocompetent hosts who are exposed to surgical or traumatic procedures are particularly susceptible to a bacterial insult because of an excessive inflammatory response affecting cell-mediated immunity.\(^{26}\) In addition to acute changes in immune status, other challenges faced by the critically ill population include perioperative glucose management. Hyperglycemia (blood glucose greater than 150 mg/dL), which can impair macrophage chemotaxis and function, has been shown to occur in patients in the perioperative setting and to increase the likelihood of postoperative infections.\(^{27}\)

Colonization with virulent pathogens also carries an increased risk of infectious complications in the ICU. Nasal colonization of MRSA in medically ICU patients has been shown to have a significant increase in subsequent MRSA infections over that in patients not colonized with the bacteria.\(^{28,29}\)

Many critically ill patients also receive foreign devices such as central venous catheters, ventricular assist devices (VADs), cardiovascular implantable electronic devices (CIEDs), and neurosurgical devices,\(^ {30,31}\) which may be prone to the formation of biofilm. Although data are sparse regarding the ability of perioperative prophylaxis to affect biofilm development in all device implantation,
using effective preoperative antibiotics may be important to minimize the risk of any inoculum propagating biofilm after surgery.\textsuperscript{31,32}

Although critically ill patients are perhaps at a greater risk of infection related to surgical procedures, this population is also susceptible to other infectious complications because of patients’ various risk factors. Prophylactic antibiotic regimens in this population have been shown to reduce infectious complications. This review is intended to focus on specific ICU indications for antimicrobial prophylaxis and, in addition to ICU procedures, the need for antimicrobial prophylaxis that has not been fully elucidated in previous literature or guidelines. It is not intended to be fully comprehensive in addressing all potential ICU infections.

\section*{ANTIBIOTIC PROPHYLAXIS IN ICU PATIENT POPULATIONS}

\subsection*{Prophylaxis in Nonsurgical ICU Patients}

\subsubsection*{Spontaneous Bacterial Peritonitis Prophylaxis}

Spontaneous bacterial peritonitis (SBP) is a common complication of cirrhotic ascites that causes inflammation and infection of the abdominal cavity membrane. It affects more than 10\% of patients admitted with cirrhotic ascites\textsuperscript{33-35} and has an attributable mortality rate of up to 50\%,\textsuperscript{36} with a higher risk of death if the infection occurs within 48 hours of a variceal bleeding event.\textsuperscript{34} Patients with cirrhosis who present with suspected SBP are recommended to be promptly initiated on appropriate antibiotic therapy, but the outcomes associated with empiric antibiotic initiation have been more compelling in the resolution of infection than in having an impact on mortality.\textsuperscript{35} Empiric antibiotic therapy for SBP is warranted if at least one risk factor is present, including (1) temperature greater than 37.8°C, (2) abdominal pain or tenderness, (3) acute mental status changes, or (4) polymorphonuclear leukocytes greater than 250 cells/mm\textsuperscript{3} in the ascitic
Patients with cirrhosis having no outward indication for empiric SBP treatment should be evaluated for the inclusion of SBP prophylaxis. Spontaneous bacterial peritonitis prophylaxis has not only been shown to reduce the risk of infections by 30%, but has also delayed the development of hepatorenal syndrome, reduced variceal rebleeding, and improved patients’ hemodynamics and has shown a mortality benefit. Because of concerns that the widespread use of antibiotics in all patients with cirrhosis may lead to subsequent colonization with multidrug-resistant organisms, the AASLD (American Association for the Study of Liver Diseases) guidelines have provided specific indications for the provision of SBP prophylaxis. Their recommendations and level of support can be seen in Table 18.2.

The most common isolated organisms during cirrhotic bleeding events are aerobic gram-negative bacilli of enteric origin including E. coli and Klebsiella sp., but gram-positive organisms have also been isolated. Few studies have evaluated various antibiotics and regimens regarding prophylaxis against SBP. Norfloxacin was once the preferred agent for SBP prophylaxis, but ceftriaxone (1 g daily) has been proven superior in the setting of cirrhosis complicated by gastrointestinal (GI) bleeding and is recommended as initial intravenous prophylaxis. Prophylaxis for SBP should continue for 7 days in patients who present with an acute GI bleed, but once the patient can take oral medications, transitioning to an oral twice-daily norfloxacin regimen would be appropriate. Norfloxacin is not available in the United States; thus, ciprofloxacin 500 mg daily orally can be used. In summary, ceftriaxone 1 g daily or ciprofloxacin 500 mg daily for 7 days is recommended for SBP prophylaxis.

**Fungal Prophylaxis**

Although a relatively rare occurrence, the development of an invasive fungal infection in the ICU portends high mortality, particularly with delays in effective treatment. Overall mortality may reach 60%,
with outcomes worse in medical patients than in surgical patients.\textsuperscript{45,47,48} Preexisting diabetes mellitus, concurrent immunosuppression, mechanical ventilation, and temperatures greater than 38.2°C are associated with increased mortality.\textsuperscript{49} In ICU patients without neutropenia, the incidence of fungemia is less than 0.5%, with most cases attributable to Candida spp.\textsuperscript{48,49} Because of the considerably poor outcomes observed in these infectious insults, initiating early appropriate antifungal therapy is of paramount importance for success. To aid in identifying patients at risk of fungal infections, research efforts have investigated the use of clinical prediction tools to identify patients who may empirically benefit from antifungal prophylaxis.\textsuperscript{50-54} These clinical prediction tools have collated various risk factors for invasive candidiasis found in ICU patients without neutropenia. Common risk factors identified by these studies include colonization with Candida spp.,\textsuperscript{53,55} con-current antibiotic use,\textsuperscript{52,55} surgical procedures,\textsuperscript{53} the presence of a foreign device,\textsuperscript{55} acute kidney injury or dialysis,\textsuperscript{52,55} prolonged intubation,\textsuperscript{50} and increased severity of illness,\textsuperscript{56} among others. Each prediction tool is different because each incorporates different variables into its risk assessment; thus, each tool has variations in both sensitivity and specificity to predict the critically ill patients who would benefit from antifungal prophylaxis.\textsuperscript{50-54,56} Several of these prediction tools have not been validated in prospective multicenter trials. In addition, several have failed to consistently predict infection, and their potential role as standard surveillance for the general critically ill population remains undetermined.

Patients having ≥ 1 episode of SBP

Patients with concurrent ascites AND aseptic fluid protein > 1.5 g/dL with concurrent renal dysfunction (creatinine > 1.2 mg/dL; BUN > 25 mg/dL or serum sodium < 130 mEq/L) or liver failure (Child-Pugh score > 9 and bilirubin > 3 mg/dL)

Eight major prospective studies have evaluated fungal prophylaxis in the critically ill population. Although specific trials and subsequent meta-analyses have shown a reduction in the incidence of Candida infections after fungal prophylaxis in the ICU, survival benefits have been equivocal and have mainly been shown in surgical/trauma ICU patients. High-risk surgical patients, particularly those with intestinal perforations or anastomotic leaks, have benefited from empiric prophylactic antifungal therapy. A small study evaluated 49 patients with recurrent GI perforations or anastomotic leakage treated with intravenous fluconazole 400 mg/day or placebo. The investigators showed a significant decrease in Candida peritonitis (4% vs. 35%) and Candida infections (9% vs. 35%) in the fluconazole arm of the study. In addition to these high-risk surgical patients, routine prophylaxis is beneficial in these patients after solid organ transplantation, or in patients with neutropenia. Otherwise, routine prophylaxis in the ICU is only recommended if a patient’s risk is presumed to be greater than 10%. Fluconazole dosed at 400 mg daily is the preferred prophylactic agent of choice as described by the 2009 Infectious Diseases Society of America (IDSA) guidelines, but there is evidence that fluconazole resistance may be emerging (these guidelines are currently under
In an effort to curb Candida resistance to azole therapy and optimize the benefits of fungal prophylaxis, there may be utility in analyzing institution-specific risk factors for invasive fungal infections and applying necessary prophylactic antifungals according to local culture data including albicans and nonalbicans Candida spp. A study of prophylaxis showed a favorable outcome with oral fluconazole versus placebo in 260 critically ill surgery patients with greater than a 3-day expected length of stay. The patients who received fluconazole had a statistically lower rate of Candida infections; however, this did not occur until day 14, when only 20 patients remained in the study. A more recent study examined the impact of caspofungin prophylaxis versus placebo followed by preemptive therapy for invasive candidiasis in high-risk adults in the ICU. A total of 222 patients who were in the ICU for at least 3 days; who were mechanically ventilated; who received antibiotics, with central line present; and who had at least one other risk factor were included in the study. The primary end point was proven or probable invasive candidiasis. The caspofungin arm of the study had lower or proven invasive candidiasis, but this was not statistically significant, nor was the overall mortality of 16.7% and 14.3% in the two study arms. At this time, prophylactic, presumptive, or even empiric therapy cannot be routinely recommended in the ICU patient. For patients with GI leakage into the abdominal cavity or those with an overall calculated fungemia risk of 10% or higher, fluconazole 400 mg intravenously daily can be recommended for prophylaxis.

**Hematopoietic Cell Transplantation**

Hematopoietic cell transplantation (HCT) is a therapeutic option for many bloodborne syndromes including lymphoma, leukemia, myelodysplastic syndrome, myeloproliferative disorders, and autoimmune conditions, among others. Transplanted hematopoietic stem cells can be obtained from the recipient patient (autologous HCT) or from another donor (allogenic HCT). Hematopoietic cell transplantation is often preceded by either a myeloablative or a nonmyeloablative conditioning regimen that is facilitated to eradicate malignant cells of the offending disease process.
and prevent rejection of an allogenic stem cell transplant. Myeloablative and nonmyeloablative therapies differ in their chemotherapeutic intensity depending on the specific type of conditioning regimen and respective malignant disorder. Consequently, these regimens vary in their degree of cytotoxicity and bone marrow suppression. Substantial pancytopenia is commonly precipitated by these conditioning regimens, placing patients at an increased risk of infection. In addition to neutropenia, these immunosuppressive regimens can cause damage to normal mucosal barriers and further increase the infectious risks of HCT recipients.69

After a patient’s initial conditioning therapy and subsequent HCT, the infectious pathogenic risks change as each patient’s immune system recovers and specific immune-regulating cell lines are regenerated. Early after the conditioning phase, patients are at the highest risk of an infection caused by gram-negative bacteria or Candida spp. Compelling factors that may contribute to infectious threats include the type of transplant (autologous HCT vs. allogenic HCT), severity of the patient’s underlying malignant disorder, degree of donor matching, and time from conditioning therapy to the patient’s stem cell transplant. As patients recover from their neutropenia and progress further from transplantation, their infectious risk profile shifts from predominant bacterial causes to viral and invasive fungal pathogens as the cellular-mediated immunity remains deficient.68 The long-term prophylactic regimens necessary for managing these risks will be discussed elsewhere in this book, and the prophylactic strategies described in this chapter will focus on the immediate posttransplant period.

Immediately after stem cell infusion, patients should receive an antibiotic with gram-negative coverage. Levofloxacin 500 mg orally daily is recommended and should continue until a patient’s neutropenia has resolved.68,70 Evidence does not support the inclusion of broad-spectrum gram-positive agents to the initial prophylactic regimen. The understanding and application of local bacterial resistance patterns should be used when deciding on a prophylactic strategy. If a patient has had recurrent MRSA infections, mupirocin has been used to reduce the MRSA burden by applying the ointment twice daily for 5 days.
directly to the nares or to any visible wounds for up to 2 weeks, but this strategy has insufficient evidence to recommend universally.68

Anti-infective Prophylaxis After Neutropenia

Neutropenia is defined as a reduction in the absolute neutrophil count (ANC) in a patient’s peripheral blood. Although neutropenia can occur secondary to autoimmune disorders,71,72 the focus of this section will be directed at neutropenia experienced in patients with cancer, which can be defined as an ANC less than 500 cells/m^3.73 After a course of chemotherapy or a bone marrow transplant, patients are at an increased risk of life-threatening infectious complications, particularly when profound neutropenia (ANC less than 100 cells/m^3) exists. Bodey and colleagues showed that in patients with leukemia having an ANC less than 100 cells/m^3, there was an overall risk of 43 infectious episodes per 1,000 patient-days.74

During neutropenia, infectious insults are often recognized by observing a patient’s temperature because fever continues to be detectable early in a neutropenic infection.75 Fever, defined as a single temperature of 38.3°C or greater for 1 hour by the Infectious Diseases Society of America (IDSA)73 and the National Comprehensive Cancer Network (NCCN) guidelines,70 can be realized in up to 50% and greater than 80% of patients who receive chemotherapy for solid tumors and hematologic malignancies, respectively.73

Despite the high rates of febrile episodes, less than 30% of these patients will have a verified clinical infection during the period of febrile neutropenia.73 Gram-positive organisms, particularly coagulase-negative staphylococci, have become the most common organisms isolated in bloodstream infections in patients with neutropenia.76 Gram-negative pathogens including E. coli, Klebsiella sp., Enterobacter sp., and other Enterobacteriaceae are isolated less commonly but are associated with a higher mortality rate than are gram-positive bacterial infections in the neutropenic population.73

Although the definitive yield of infectious cause may be poor, prompt and appropriate treatment of patients who develop febrile neutropenia
is imperative to improve outcomes, with improvements in mortality observed with early antibiotic initiation on detection of fever in the patient with neutropenia.\textsuperscript{77}

Although early initiation of antibiotics is critical in a patient with neutropenia and fever, preventing infection during the neutropenic phase after chemotherapy is also important. Antibiotic prophylaxis in the patient with neutropenia is recommended by the NCCN and IDSA guidelines with considerations given to low- and high-risk populations for infection. Antibiotic prophylaxis is recommended by both organizations, specifically in high-risk populations. High-risk patients are identified as those with an ANC less than 100 cells/m\textsuperscript{3} or an anticipated duration of neutropenia of greater than 7 days. The NCCN guidelines\textsuperscript{70} also encourage prophylactic antibiotics for patients being treated for multiple myeloma or chronic lymphocytic leukemia and in those who are receiving a purine analog as their chemotherapeutic agent.\textsuperscript{70}

Fluoroquinolones are the preferred antibacterial prophylactic agents for these patients during their high-risk period of neutropenia. Levofloxacin 500 mg daily orally has shown a reduced rate of infection and hospitalization in two randomized prospective clinical trials, but it had no mortality benefits.\textsuperscript{78,79} Adding gram-positive prophylaxis is not recommended in the initial regimen for patients with neutropenia.

Fungal prophylaxis with fluconazole 400 mg daily either intravenously or orally is warranted as well in high-risk patients with neutropenia, particularly in those who are receiving allogeneic HCT or being treated with intense chemo-therapy for remission or salvage therapy in acute leukemia.\textsuperscript{73} Prophylaxis should continue throughout neutropenia.

Prophylaxis with the antiviral agent acyclovir is recommended for patients who test positive for herpes simplex virus and have undergone induction therapy for allogenic HCT or leukemia.

Viral prophylaxis after HCT is dependent on the presence of specific viral findings in pretransplant serum testing. Prophylaxis for cytomegalovirus (CMV) infection after HCT is determined by the patient’s and donor’s serum CMV status in allogeneic HCT. For any patients who require CMV prophylaxis (CMV-seropositive HCT recipients or CMVseropositive donors), available prophylactic options
include high-dose acyclovir therapy (500 mg/m\(^2\) intravenously three times daily or 800 mg orally four times daily), valacyclovir (2 g three or four times daily), or intravenous ganciclovir. For patients who receive ganciclovir therapy, it is recommended to include induction therapy of 5 mg/kg twice daily for 5–7 days; this should be initiated when HCT occurs and then continued daily for 100 days post-HCT.\(^{68}\)

To prevent reactivation of herpes simplex virus, prophylactic acyclovir is recommended for all individuals who test seropositive before transplantation. Acyclovir 400–800 mg orally twice daily or 250 mg/m\(^2\) per dose every 12 hours intravenously should commence during the initial conditioning phase and be continued until the patient has appropriate engraftment or resolution of mucositis.\(^{68}\)

Fluconazole 400 mg orally or intravenously daily is recommended as prophylaxis for all patients receiving allogeneic HCT and for those with autologous HCT who have had intense conditioning regimens or who are experiencing mucositis. Fungal prophylaxis should ensue until at least 7 days after the ANC is greater than 1,000 cells/mm\(^3\).

**Prophylaxis in Cardiac Critical Care Procedures**

**Ventricular Assist Devices**

The rate and precision of VAD implantation has dramatically increased since the first report of an artificial ventricle in 1963. As the placement of these devices has become more common, efforts have continued to improve their longevity in addition to minimizing the associated complications. One specific improvement of note is the increasing prevalence of the implantation of continuous-flow devices such as the HeartMate II, which have shown more favorable outcomes, including infectious complications, than pulsatile-flow left ventricular assist devices (LVADs).\(^{80}\) Although data from the 2014 Interagency Registry for Mechanically Assisted Circulatory Support report indicate that infection rates for VADs have decreased, infection remains a common complication associated with VAD placement.\(^{81}\) Despite this information, there is a lack of consensus on the management of these
patients’ infectious prophylaxis, particularly in the perioperative setting.

The main infectious risks immediately after VAD implementation are driveline infections, pump pocket infections, bacteremia, and endocarditis.\textsuperscript{82} The pathogenic insults to these patients may include gram-positive organisms, gram-negative bacilli, and fungi.\textsuperscript{83,84} The principal source of inoculum comes from the skin surface, which is a primary source of staphylococcal species. These isolates have a high capacity to adhere to foreign device material and form biofilm and evade the immunological system, thereby becoming very difficult to eradicate,\textsuperscript{32,85,86} making antistaphylococcal prophylaxis of paramount importance in the perioperative period. Although staphylococcal coverage is deemed of utmost importance for VAD perioperative prophylaxis, coverage for other pathogens remains common in most VAD centers. In addition to driveline infections, surgical pocket infection is common. Because of a high mortality rate associated with fungemia, fungal prophylaxis often joins the perioperative antibiotic prophylactic regimen. In addition, coverage of gram-negative pathogens is often added.

Several studies have evaluated various perioperative antibiotic regimens in the setting of VAD placement, but inconsistent choice, timing, and duration of prophylactic antimicrobial therapy and differing definitions of LVAD infection make a direct comparison of stated infection rates difficult.\textsuperscript{87} Unfortunately, large prospective trials are lacking regarding the appropriateness of perioperative antibiotic management in VAD transplantation, and recommendations in the International Society for Heart & Lung Transplantation (ISHLT) guidelines are largely based on expert opinion. The 2013 update on perioperative management recommends broad-spectrum gram-positive and gram-negative coverage within 60 minutes of the first incision before implantation. Because of the high rate of staphylococcal driveline infections, the opinion expressed in the document calls for patients to undergo nasal swab screening for MRSA preoperatively with the desire for topical treatment with mupirocin to be incorporated if positive. Gram-negative and fungal coverage inclusion should be tailored according to institution-specific epidemiologic data, colonization
rates, and other high-risk patient-specific data. Fungal coverage may be warranted in regions known to have higher risks of virulent fungal pathogens. There are no specific recommendations on which antibiotics to choose or address toward antifungal coverage, but there is evidence that advocates against using prolonged vancomycin in high-risk general cardiac surgery patients.\(^{18,88}\) The recommended therapy duration is 24–48 hours, but the evidence with the longer duration is scarce.\(^{83}\) The optimal regimen for antibiotic prophylaxis in patients undergoing LVAD placement is not known. Guidelines indicate that a single dose of cefazolin or cefuroxime can be used before LVAD transplantation,\(^{3}\) but the 2013 ISHLT guidelines\(^{83}\) advocate for MRSA coverage with 24–48 hours of antimicrobial coverage.

Many centers use a combination of vancomycin (15 mg/kg intravenously 1 hour before surgery; then every 12 hours), rifampin (600 mg orally 1–2 hours before surgery; then every 24 hours), levofloxacin (500 mg intravenously 1 hour before surgery; then every 24 hours), and fluconazole (200 mg intravenously 1 hour before surgery; then every 24 hours) for a total of 48 hours postoperatively as recommended in the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial.\(^{89,90}\) Data analyses on the use of alternative MRSA prophylactic strategies other than vancomycin are scarce in LVAD transplantation, but if a contraindication to vancomycin exists, daptomycin may be an alternative prophylactic strategy.

**Artificial Heart Implantation**

The availability of total artificial heart (TAH) implantation has improved short-term survival rates in patients who do not meet the criteria for VAD placement or who do not have an opportunity for an immediate heart transplant.\(^{91}\) Postoperative complications, including infections, are major deterrents to the success after TAH placement. Infectious complications can occur in more than 80% of TAH recipients, potentially delaying the patient’s ability to receive a heart transplant.\(^{91,92}\) At least half of all infections occur within the first 30 days post-implantation,\(^{93}\)
but most documented infectious complications originate from pulmonary or urinary sources.\textsuperscript{92,93} In addition to these infectious insults, patients with TAH are predisposed to bacteremia, driveline infections, and superficial sternal infections, potentially because of exposure to organisms during the perioperative period. These infectious risks are notably higher than in other patients, potentially because of the nature of the mechanical device itself. A TAH system is composed of metals and polymers that are in contact with tissues and hemodynamic surfaces. These surfaces pose a medium susceptible to biofilm development that is believed to promote bacterial colonization and predicate biomaterial-centered infections.\textsuperscript{85}

Unfortunately, prophylactic antibiotic regimens are poorly described in the literature, and there are no specific recommendations for the choice of antimicrobial agent or duration of prophylaxis in the perioperative management of TAH. Because of the nature of the surgical procedure necessary for a TAH placement, antibiotic administration with agents similar to those used in other cardiac surgical procedures such as intravenous cefazolin or cefuroxime for 24 hours would be advocated. Patients with penicillin allergies should receive vancomycin or clindamycin as surgical prophylaxis.

\textbf{Extracorporeal Membrane Oxygenation Cannulation}

The prevalence of extracorporeal membrane oxygenation (ECMO) initiation has continually increased during the past 2 decades in both the neonatal and the adult critical care populations. As more adult patients have acute needs for ECMO initiation, it is evident that coinciding management strategies will have to continue evolving to improve delivery and minimize complications. Currently, infectious complications during ECMO management are the second most frequent setback after hemorrhagic issues.\textsuperscript{94} Potential issues that pose infection risks to patients initiated on ECMO therapy are the presence of several large-bore catheters that are exposed to the environment after surgical placement. In addition, depending on the selection of site of the ECMO cannulation that is chosen, infectious risks differ. Venovenous ECMO therapy typically uses a femoral access site that
may carry an additional infectious risk because of higher contamination rates similar to the placement of femoral central lines.\textsuperscript{95}

Several studies have investigated potential infections related to ECMO initiation. In a study by Aubron et al., the investigators found that 14.4\% of 146 patients had a bloodstream infection related to ECMO cannulation within 8 days of the procedure.\textsuperscript{95} Although they showed that the only independent risk of perioperative infection was related to the patient’s present severity of illness, this is not in accordance with all studies as a risk factor. The independent relationship between patient severity before ECMO initiation and bloodstream infection occurrence is controversial, possibly because of the variations in design between studies, including differences in periods and methods used for assessing severity and patient populations. Similar to TAH, there are no published standardized prophylactic antibiotic strategies or associated infectious outcomes with their use during the initiation of ECMO therapy, but using cefazolin or cefuroxime (or vancomycin or clindamycin in penicillin-allergic patients) would be appropriate, especially in the setting of central cannulation.

Cardiac Implantable Electronic Devices

Cardiovascular implantable devices, including both PPDs (permanent pacemaker devices) and ICDs (implantable cardioverter-defibrillators), have increased in prevalence by at least 19\% and 60\%, respectively, since 1999,\textsuperscript{96} with more procedures being done in older patients with more comorbidities.\textsuperscript{96,97} As the overall patient age and acuity of these device recipients continues to increase, there is an increasing probability that critical care practitioners will provide care to this population after a new cardiac event while these patients are in the ICU.

Two primary categories of infections are seen after CIED implantation: pocket infection and deeper infections. Pocket infection is a particular risk during CIED implantation and is most consistent with gram-positive bacteria, specifically \textit{S. aureus}.\textsuperscript{98} Overall, infectious complications after CIEDs are relatively low in the perioperative
window, but infections after the implantation of these devices portend high morbidity, costs, and mortality up to 18% at 6 months.\textsuperscript{98} Like other cardiovascular devices, CIEDs have the risk of biofilm development, which can contribute antibiotic resistance.\textsuperscript{98} These devices can also become infected secondary to bacteremia or intraoperative contamination.

To minimize the risk of perioperative infection with CIED placement, it is recommended to administer a parenteral antibiotic within 1 hour of the procedure. This is supported by findings from a double-blind randomized trial in which preoperative cefazolin had a postoperative infection rate of 0.63% compared with 3.28% without prophylaxis.\textsuperscript{99} Additional support for preoperative antibiotics can be seen in two multivariate analyses,\textsuperscript{100,101} both of which have shown preoperative antibiotics to have a protective effect against infections after CIED. A one-time dose of cefazolin or cefuroxime (vancomycin or clindamycin for $\beta$-lactam allergy) given within 1 hour of the procedure is sufficient prophylaxis before CIED placement.

**Prophylaxis in Neurocritical Care Procedures**

Neurosurgical procedures are stratified into one of five categories according to a neurosurgical classification score investigated by Narotam and colleagues (Table 18.3).\textsuperscript{102} The classification system delineates variation in infectious risks according to the type of neurosurgical procedure. Clean neurosurgical procedures carry the lowest infection risk (1.9%–5.8%)\textsuperscript{102-104} if perioperative antimicrobial prophylaxis is used. The absence of antibiotic prophylaxis has been shown to increase the risk of postoperative infections by up to 10% in this patient population.\textsuperscript{103,104}

Specific risk factors can compound the likelihood of postoperative infections in neurosurgical patients. Diabetes mellitus, emergency surgery, prolonged procedural times, cerebrospinal fluid (CSF) leaks, or the surgical placement of a foreign body increases the infection risk. Neurosurgical infectious complications are typically attributed to either superficial SSIs or the development of deeper central nervous system
(CNS) infectious such as meningitis, epidural abscesses, or subdural empyemas.\textsuperscript{105,106} Antimicrobial prophylaxis has resulted in lower postoperative infections when perioperative antibiotics are included in low-risk neurosurgical procedures. The American Society of Health-System Pharmacists and Society for Healthcare Epidemiology of America (SHEA) guidelines for surgical guidelines for antibiotic prophylaxis recommend a single dose of antibiotic within 60 minutes before the incision.\textsuperscript{3} There is no overall consensus on the choice of antibiotics in the neurosurgical population.\textsuperscript{107} Perioperative antibiotics should be directed at gram-positive organisms such as S. aureus and coagulase-negative staphylococcus, which account for most infectious insults.\textsuperscript{108,109} Gram-negative organisms are less commonly reported but are indicated in up to 20% of cases. Pseudomonas aeruginosa and other resistant gram-negative organisms' prevalence is indicated in less than 5% of cases.\textsuperscript{104} Antibiotic selection should include an agent active against gram-positive organisms and ideally tailored to local resistant and susceptibility patterns. A common antimicrobial used for prophylaxis in neurosurgical procedures includes cefazolin, or vancomycin if severe allergy or if MRSA resistance rates are high at the individual institution.

\end{tabular}
\caption{Narotam Classification of Neurosurgical Procedures}
\end{table}
Dirty Procedure occurring during sepsis at the time of operation; confounding infection including abscess, subdural empyema, ventriculitis, osteitis, or skin infection

In addition to clean neurosurgical procedures, surgical procedures that involve the placement of foreign devices for intracranial monitoring or CSF shunting are common in the critically ill population.\textsuperscript{110} These devices have been indicated as specific risks of postoperative infection in the neurosurgical population.\textsuperscript{109,111,112}

**Intracranial Pressure (ICP) Monitoring and CSF Shunting Devices**

External ventricular drains are commonly used for CSF diversion from the cranial space as well as for intracranial pressure (ICP) monitoring in the setting of traumatic brain injury, intracranial hemorrhage, or hydrocephalus. Although these devices are used for monitoring and management, they portend infectious complications cumulating around 10\%,\textsuperscript{113} with the incidence of infection increasing with prolonged ventricular catheterization.\textsuperscript{112,113} Similar to the microbiologic sources seen in the clean procedural infections, most pathogenic organisms are gram-positive cocci.\textsuperscript{113} Studies supporting the routine use of prophylactic antibiotics in these populations are equivocal. Retrospective analyses have shown no benefit with prophylactic antibiotics over no prophylaxis after ICP placement in infectious outcomes.\textsuperscript{112,114} The provision of broad-spectrum perioperative antibiotics (ceftriaxone or ciprofloxacin) has also not been advantageous versus narrow-spectrum antibiotics (cefazolin or vancomycin) after ICP placement.\textsuperscript{115} In addition, it has been shown that either broad-spectrum antibiotics or prolonged use of antibiotics may expose patients to resistant gram-negative organisms in future infections.\textsuperscript{114,115} To contrast these findings, however, two meta-
analyses have shown a reduction in infection rates using antibiotic prophylaxis in CSF shunting procedures.\textsuperscript{116,117} Antibiotic-impregnated shunts are available for use, but further data may be needed before universal use.\textsuperscript{3} Because of the high risk of complications associated with a CSF-related infection and available data, the SHEA surgical antibiotic guidelines committee gave a level A recommendation for a one-time preoperative dose of cefazolin before shunting procedures.\textsuperscript{3} Clindamycin and vancomycin are recommended for patients allergic to penicillin.

**Subdural Grids**

Subdural grid placement may occur in a select set of patients with a history of intractable antiepileptic medication-resistant epilepsy,\textsuperscript{118} which often requires close observation, possibly in a neuro-ICU. Placement of a subdural grid with depth electrodes for seizure foci identification is done by craniectomy. By definition, this is a clean procedure with a foreign body implantation and carries more than a minimal risk of perioperative infection as classified by Narotam et al.\textsuperscript{102} There currently are no guidelines or specific recommendations for antibiotic coverage during the placement and period of subdural grid. A meta-analysis involving 21 studies (20 retrospective) indicated that although the overall prevalence of neurologic infections is relatively low, they are the most commonly identified complication in these cases. Particular infectious insults were described as superficial surgical infections (3%), pyogenic neurologic infections (2.3%), and CSF bacterial colonization (7.1%). Thirteen of the 21 studies indicated that systemic antibiotics were administered, but the choice of antibiotics and duration of use were variable, with cephalosporins being the most likely used antibiotic class. Prophylaxis is extended for the duration of the subdural grid placement in most cases. Because of the paucity of randomized trials of antibiotic prophylaxis, a standard recommendation cannot be made at this time, but antibiotics with adequate CNS penetration that target superficial gram-positive flora such as cefazolin or cefotaxime would be reasonable while the subdural grid is in place.
Prophylaxis in Unique ICU Procedures

Antibiotics at Intubation

Patients who are intubated during their ICU stay have an increased risk of developing pneumonia. Ventilator-associated pneumonia (VAP) may occur in up to 15% of ventilated patients and portends worse outcomes such as longer length of stay, increased costs, and higher mortality rates.\textsuperscript{119} The estimated mortality associated with VAP may be as high as 10%.\textsuperscript{120}

Identified risk factors for VAP include concurrent organ failure, age older than 60, prior antibiotic exposure, and failure to elevate the head of the bed after intubation.\textsuperscript{121} Although the inoculum responsible for VAP commonly comes from pathogens that are colonized in the oropharynx and upper GI tract, targeted bacteria should be based on a patient’s medical history, prior antibiotic exposure, and institutional microbial patterns.\textsuperscript{122}

Specifically recommended prophylactic measures for VAP include the coordination of daily interruption of sedation and spontaneous breathing trials, incorporation of early mobility measures, use of noninvasive mechanically ventilation when possible, and changing of the ventilator circuit only when necessary.\textsuperscript{123} Although there is moderate evidence for using both prophylactic probiotics and chlorhexidine-based oral care in mechanically ventilated patients, evidence remains sparse describing the utility of prophylactic antibiotics during intubation or mechanical ventilation.

Some trials have investigated the benefit of prophylactic antibiotics post-intubation. Cefuroxime given as prophylaxis for two doses after intubation had a protective effect against early-onset VAP in patients with head injury.\textsuperscript{124} Another prospective trial that studied the impact of a single dose of ceftriaxone, ertapenem, or levofloxacin given before intubation showed a reduction in the incidence of early-onset VAP. However, it showed no benefit regarding late-onset VAP, tracheobronchitis, or mortality.\textsuperscript{125} Neither of these single-center trials assessed the impact on developing resistant pathogens, possibly
overlooking any ramification on antimicrobial stewardship efforts. The SHEA guidelines do not address the utility of prophylactic antibiotics in VAP.\textsuperscript{123} Because of the absence of larger multicenter randomized trials, the delivery of prophylactic antibiotics at intubation cannot be recommended.

**Nasal Packing**

Although epistaxis is a relatively normal occurrence at some point in a patient’s lifetime, only 6% of these events result in the need for medical attention,\textsuperscript{126} and many bleeding events occurring in the anterior septum are self-limiting. For the patients who have bleeding events that require nasal packing, however, there may be a need for more aggressive management and closer observation, occasionally in the ICU. Complications that can ensue after nasal packing include aspiration, angina, myocardial infarction, respiratory distress, and hypoxia.\textsuperscript{126-128} Patients with nasal packing are also at an increased risk of toxic shock syndrome (TSS), an insult that is rapidly precipitated after toxin production by colonized \textit{S. aureus} in the nasal membranes. Although the rate of TSS is reportedly low in postoperative nasal packing (16 per 100,000 packings), antibiotics are routinely prescribed to these patients.\textsuperscript{129} However, there has been no clear evidence that using antibiotics reduces the rate of \textit{S. aureus} infection, rates of nasal colonization, or episodes of TSS.\textsuperscript{130-132} Antimicrobial prophylaxis may not be necessary for TSS prophylaxis in the setting of nasal packing, but if used, agents that have antistaphylococcal activity such as amoxicillin/clavulanate 500 mg orally three times daily or cephalexin 500 mg orally twice daily could be considered for the duration of the nasal packing.

**SUMMARY**

Because of the increased risk of adverse events attributed to SSIs, adherence to antimicrobial prophylactic strategies in the critically ill population is of paramount importance and should be directed by best practices. Pharmacists practicing in an ICU environment should be
aware of the surgical risks and necessary precautions to minimize poor outcomes in many unique surgical and non-surgical scenarios. Various recommendations have been provided throughout this chapter according to the available evidence and guidelines, but the chapter does not provide insight into all potential ICU procedures or infectious events. However, this chapter can serve as a guide to the ICU clinician when fully elucidated recommendations may not be available in other available guidelines.

Section 3

Neurocritical Care
LEARNING OBJECTIVES

1. Identify risk factors for seizures in critically ill patients.
2. Recommend appropriate dosing and monitoring of urgent and emergent therapy.
3. Compare and contrast antiepileptic agents used in the management of status epilepticus (SE).
4. Customize drug therapy management in special populations with altered pharmacokinetic parameters.
5. Develop a patient-specific treatment algorithm for the management of refractory SE in intubated and non-intubated patients.

ABBREVIATIONS IN THIS CHAPTER

cEEG  Continuous electroencephalogram
EEG   Electroencephalogram
INTRODUCTION

Seizures are a serious medical complication of the central nervous system (CNS) that can lead to considerable morbidity and mortality. They can occur along a spectrum of syndromes, from the focal seizure to status epilepticus (SE), which in turn can evolve into refractory status epilepticus (RSE) and super-refractory status epilepticus. Most isolated seizures are self-resolving, but any seizure that persists beyond 5 minutes or a series of seizures between which a patient does not regain consciousness should be considered SE. In intensive care units (ICUs), this diagnosis may be difficult to make because of severe underlying neurological disease or drugs that may mask outward signs of seizures. Although outcomes are improved with faster identification and timely pharmacologic treatment, clinicians are still challenged by the hemodynamic instability, numerous drug interactions, and end-organ dysfunction often seen in critically ill patients. Several guidelines have been published to help promote evidence-based practice, but the ICU remains a challenging area. Use of published algorithms and pathways and development of institutional protocols can expedite treatment to terminate SE.

This chapter will focus on the treatment of SE in critically ill patients with a brief discussion of the role of seizure prophylaxis. The goals of therapy for SE are to (1) rapidly terminate seizure activity, both
physiologic and electrographic; (2) identify and treat the cause, if possible; and (3) prevent future seizures, if needed, with the appropriate use of anticonvulsants.

**EPIDEMIOLOGY**

A recent study described the epidemiology of SE in the United States over 12 years.\(^4\) Although an increase in incidence was seen (3.5–12.5 per 100,000), there was no change for in-hospital mortality. This increased incidence may have occurred partly because of the change in definition of SE as well as increased use of electroencephalogram (EEG) monitoring and, therefore, SE diagnosis during the past decade.\(^5\) A higher incidence of SE was seen at each end of the age spectrum (younger than 10 years and older than 50 years), but in-hospital mortality was much higher for older adults than for children (20.2% vs. 2.6%). Men have higher incidence and mortality rates than do women; men also have SE at a younger age. Racial disparities are seen in SE, with a higher incidence among blacks (13.7 per 100,000) than among whites (6.9 per 100,000), although in-hospital mortality rates are higher for whites (10%; 95% CI, 9.8–10) than for blacks (7.4%; 95% CI, 7.3–7.6). The number of patients discharged to home declined over time, whereas discharge to long-term care facilities almost doubled.

Most seizures occurring in ICU patients are convulsive in nature—around 90% in a recent series of medical and surgical patients,\(^6\) although 50% of these patients had a history of epilepsy. Hospital mortality was reported to be 21% and was highly predicted by age, lower Glasgow Coma Scale score at baseline, and severity of SE. Treatment of SE in a neuro-ICU versus a medical ICU did not result in decreased mortality or morbidity or a shorter length of stay,\(^7\) although the use of continuous electroencephalogram (cEEG) monitoring was greater in the neuro-ICU.

Mortality for SE has been reported to be around 4% for inpatients with generalized tonic-clonic SE.\(^8\) Additional mortality risk factors include mechanical ventilation, female sex, comorbidity index, and
anoxic brain injury. Other cohort studies report higher case fatality rates of around 22%, but they include all types of SE. Increasing age and anoxic brain injury continue to be driving contributors for death after SE and are commonly seen in ICU patients. Status epilepticus after CNS infection also confers a poor prognosis. Patients without epilepsy who develop SE tend to have worse outcomes.  

**ETIOLOGY**

Seizures in the ICU can arise from existing neurological conditions or as a complication of systemic illness (see Table 19.1). Neurotrauma, stroke, CNS infections or tumors, and epilepsy are common neurological etiologies of SE. Hypoxia, substance abuse/toxicity, drug-drug interactions, renal or hepatic dysfunction, and acute metabolic disturbances may also lead to the development of SE in the critically ill patient. Electrolyte imbalances are common in ICU patients, and acute fluctuations in sodium, calcium, and magnesium can lead to seizure activity. Drugs may also be implicated in acute seizures. Bupropion, diphenhydramine, tricyclic antidepressants, tramadol, amphetamines, isoniazid, and venlafaxine have all been implicated in seizures or SE in overdose cases. A clinical tool was recently developed to aid clinicians in evaluating potential etiologies in patients with SE, which may result in more timely treatment and resolution. The most common determinants for SE included subtherapeutic anticonvulsant concentrations, brain tumors, acute intracerebral hemorrhage, history of epilepsy, infection (both CNS and systemic), traumatic brain injury, alcohol withdrawal/intoxication, and benzodiazepine withdrawal.

| Table 19.1 | Etiology and Selected Prevalence and Mortality in Status Epilepticus |
Traditionally, the cause of SE has been described as an imbalance of excitatory and inhibitory neurotransmitter activity in the CNS. It may be a condition of excess excitation, insufficient inhibition, or a combination of both. Clinically, it is difficult to differentiate, but current treatments focus on increasing overall inhibitory activity. Glutamate, substance P, and neurokinin B are the more common excitatory neurotransmitters, whereas γ-aminobutyric acid (GABA) and neuropeptide Y moderate neuronal inhibition. Most isolated seizures occur when inhibitory
mechanisms are transiently overwhelmed.

Glutamate normally produces depolarization of neurons through its effects on postsynaptic N-methyl-d-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA) receptors. γ-aminobutyric acid mediates postsynaptic hyperpolarization through the opening of chloride channels. More recent literature has shed light on additional mechanisms and potential treatment strategies.

An alteration in GABA activity over time may explain the refractoriness of GABA-ergic drugs as SE progresses. Internalization of synaptic GABA<sub>A</sub> receptors has been reported to increase with ongoing seizure activity, resulting in the decreased efficacy of benzodiazepines as well as other GABA-ergic drugs. Clinically, this pharmacoresistance begins soon after seizures begin, persists beyond 30 minutes, and may contribute to increased morbidity in these patients because of delayed diagnosis and proper intervention. Use of benzodiazepines early on in SE may be successful, but response quickly declines as time progresses between onset and treatment. This highlights the importance of rapidly identifying seizure activity with immediate administration of benzodiazepines to optimize control, followed by urgent and refractory treatments as necessary.

Distinct physiological phases are seen with classic generalized tonic-clonic SE. Within 10 minutes of seizure activity (early or phase I), increases in serum concentrations of norepinephrine and epinephrine as well cortisol can be seen, leading to cardiovascular hyperactivity (e.g., hypertension, tachycardia, and arrhythmias), fever, and hyperglycemia. Prolonged muscle contraction from uncontrolled tonic-clonic convulsions results in lactic acid production, and subsequent acidosis can be severe. Normally, this resolves once convulsions stop, but in critically ill patients with an underlying acidosis from other conditions or compromised tissue perfusion, it may persist and warrant further therapy.

After 30 minutes of continuous seizing (late or phase II), systems begin to fail as compensatory mechanisms are overwhelmed. Hypotension, bradycardia, and hypoglycemia can be seen; cerebral perfusion pressure is compromised as mean arterial pressure falls,
whereas cerebral demand remains high because of unrelenting 
electrical activity. In critically ill patients with poor reserve or 
unrecognized SE, this phase may occur earlier and require emergent 
treatment. Unrelenting tonic-clonic activity can lead to rhabdomyolysis 
and subsequent renal failure.\textsuperscript{19}

**DIAGNOSIS**

Timely clinical identification of SE is important because of the time-
sensitive response of treatment strategies. Most generalized seizures 
in the ICU are well recognized,\textsuperscript{20} but it can be difficult to detect subtle 
seizure types such as non-convulsive status epilepticus (NCSE) where 
the traditional tonic-clonic movements of the extremities are not visibly 
apparent (Table 19.2). A cEEG is a useful tool in these cases to help 
identify such patients and direct therapy. Any unexplained acute 
changes in mental status should be investigated with EEG for evidence 
of seizure activity. Patients who lack response to drug therapy will also 
benefit from EEG monitoring. Figure 19.1 and Figure 19.2 represent 
EEG findings in patients with convulsive and non-convulsive seizures, 
respectively.

PROPHYLAXIS

For patients with known risk factors for seizures, prophylactic therapy can reduce the risk of SE. In patients with provoked SE, it is essential to treat both the seizure and the underlying cause. For some ICU patients, it may be difficult to assess the cause of the SE because of several risk factors and difficulty in identifying the exact onset of the seizure activity. Some etiologies such as anoxic brain injury, most commonly seen after cardiac arrest, are more difficult to treat and tend to have poorer outcomes.\textsuperscript{20}

Certain ICU patients at high risk of seizures should receive short-term prophylaxis (e.g., traumatic brain injury and aneurysmal subarachnoid hemorrhage; see Table 19.1). Guidelines have been published to identify high-risk populations, describe the risk of seizures after brain injury, and recommend suitable timing of therapy.\textsuperscript{21} Seizures, and potentially SE, may occur in these patients if dosing is not optimized, prophylaxis is not initiated in a timely manner, or therapy is interrupted or inadvertently altered (e.g., drug interactions). Prophylaxis should only be provided during the high-risk period and discontinued afterward unless actual seizures occur because these agents are not without considerable adverse effects. ICU patients who are pharmacologically sedated and paralyzed should remain on seizure prophylaxis until these agents are cleared systemically because of the possible masking of any physiologic signs of seizures unless cEEG monitoring can confirm the absence of seizure activity.

TREATMENT

The treatment of SE is complex, often requiring the use of multiple agents, drugs with narrow therapeutic indexes, aggressive dosing targeting higher serum concentrations, and frequent titrations to a goal of seizure cessation. Although a variety of treatment options are available, evidence is lacking to support one treatment strategy over another. Many of the current treatment data are from non-randomized, retrospective studies that have small sample sizes and lack standardized dosing strategies and treatment durations. Newer
anticonvulsants have easier, non-weight-based dosing, fewer drug interactions, and better adverse event profiles. Although they may be more desirable, the data surrounding their use, particularly as first-line agents, are less robust than for historical agents. These agents were also excluded from many of the earlier comparator trials. Regardless of which drugs are selected, the primary treatment goal remains the same: cessation of seizures, including clinical and subclinical (electrographic) seizures. Management of airway, breathing, and circulation should occur simultaneously with targeted treatment for SE. Other goals include achievement of therapeutic drug concentrations, liberation from mechanical ventilation (particularly if the initial treatment required respiratory support), identification and treatment of the underlying cause, and selection of regimens that produce acceptable adverse effect profiles. Emergent therapy should be initiated within the first 5 minutes of seizure onset and urgent control treatment, immediately after or within the first 10 minutes of seizure onset.

![EEG of patient with tonic-clonic seizures. Normal brain waves are seen initially followed by evidence of seizure activity.](image)
It is important to be familiar with all available agents so that an individualized, stepwise approach to the treatment of SE can be selected. Pharmacologic options may be classified as emergent, urgent, and refractory and are generally initiated in this order, although sometimes, the addition of a drug or the titration of a continuous infusion occurs simultaneously. Table 19.3 describes the most commonly used drugs for SE.

Emergent Initial Treatment: Benzodiazepines

Benzodiazepines, GABA receptor agonists, are considered first-line agents in the treatment of SE. Lorazepam, midazolam, and diazepam are the most commonly used benzodiazepines, and all are available intravenously. When used emergently for SE, intravenous benzodiazepine administration is preferred; however, nasal, buccal, or rectal routes are acceptable alternative routes of administration. Historically, drugs such as midazolam and diazepam were preferred for their ability to quickly cross the blood-brain barrier; however, they carry a risk of rebound seizures because of their rapid redistribution out of the brain and into adipose tissue. Intravenous lorazepam, a less lipophilic benzodiazepine than diazepam, is the preferred first-line treatment for SE. A randomized trial comparing lorazepam (2–4 mg), diazepam (5–10 mg), and placebo for out-of-hospital SE found an SE termination rate of 59%, 43%, and 21%, respectively. Although the only statistically significant difference was between both benzodiazepines and the placebo group, there was a trend toward faster termination and better control of SE in the lorazepam group. Another study found numerically better success rates with lorazepam 2 mg over diazepam 5 mg (78% vs. 58% seizure termination after one dose), but the results were not statistically significant. Similar results were seen after two doses of each drug; a total of 4 mg of lorazepam and 10 mg of diazepam terminated seizures in 89% and 76%, respectively. The VA Cooperative Trial compared four different treatment regimens (lorazepam, phenobarbital, diazepam plus
phenytoin, and phenytoin) and found that lorazepam was more successful than phenytoin in overt status cases (64.9% vs. 43.6%; \( p=0.002 \)). Because of the formulation of lorazepam and diazepam with propylene glycol, midazolam is the preferred agent when given intramuscularly. In a randomized controlled trial, midazolam 10 mg intramuscularly was found as effective as lorazepam 4 mg intravenously for prehospital seizure control.\(^\text{27}\) Diazepam is preferred for rectal administration, although this route should only be used when intravenous and intramuscular options are unavailable or contraindicated.\(^\text{3}\) Although respiratory depression is a concern with benzodiazepine administration, studies have shown no difference in respiratory depression compared with placebo and non-benzodiazepines when administered for SE.\(^\text{22,25}\)

**Urgent Control Treatment**

Urgent treatment uses non-benzodiazepine anticonvulsants. Drugs are initiated in a stepwise fashion and quickly titrated to therapeutic doses. No prospective, comparative data past the first benzodiazepine and non-benzodiazepine drug combination suggest the superiority of any third-line agent. Because of the suboptimal success rate with second and third anticonvulsants, some prescribers opt to skip urgent control treatment and move directly to continuous infusions, whereas others may initiate anticonvulsants concurrently with continuous infusions. Regardless, most prescribers will at least administer one anticonvulsant after the initial benzodiazepine before ordering a continuous infusion.\(^\text{28}\) This option is especially desirable in non-intubated patients who may benefit from a trial of anticonvulsants in order to avoid the intubation required for most anesthetic infusions. Urgent therapy with anticonvulsants often requires bolus dosing, rapid and aggressive titration, and, at times, addition of several drugs concomitantly or in rapid succession. Dose adjustments for renal or hepatic dysfunction are not required for loading doses. Because treatment delays of greater than 30 minutes are associated with a delayed response, the initiation and titration of urgent therapy should
occur rapidly. Commonly used agents are detailed in the following sections and are listed in descending order according to the amount of data surrounding their use.

**Phenytoin/Fosphenytoin**

Phenytoin is one of the most commonly studied drugs in the treatment of SE. Phenytoin is a substrate of cytochrome P450 (CYP) 2C19 (major), 2C9 (minor), and 3A4 (minor) as well as a potent CYP3A4, CYP2C19, and CYP2C9 PgP inducer. Because of its interference with major metabolic enzymes, phenytoin is associated with several drug interactions and can decrease concentrations of drugs that are
commonly coadministered in the ICU such as quetiapine, midazolam, methadone, nimodipine, and atorvastatin. Additional interactions occur with other highly protein-bound agents. Co-administration with warfarin may result in increased serum concentration of each drug. Because of its effects on sodium channels, phenytoin is considered a class 1B antiarrhythmic, and it can lead to arrhythmias and hemodynamic instability. It is formulated with propylene glycol, which further potentiates its risk of hypotension, especially with faster administration rates. Thus, the rate of administration is limited to 50 mg/minute or less.

Fosphenytoin, a prodrug of phenytoin, is often preferred to phenytoin because it is not stabilized with propylene glycol and can be administered at a faster maximum rate of 150 mg/minute. The less basic pH of the formulation decreases the risk of purple glove syndrome and phlebitis compared with phenytoin and allows for intramuscular administration. Whereas phenytoin is only compatible with normal saline, fosphenytoin is compatible with many diluents, including 5% dextrose. Phenytoin and fosphenytoin both carry other significant adverse effects including thrombocytopenia, leukopenia, and hepatotoxicity.

Phenytoin follows Michaelis-Menten kinetics, which requires thoughtful dose titration because small increases in dose may result in large, nonlinear increases in serum concentrations. For example, a simple doubling of the dose may lead to an exponentially higher-than-expected drug concentration, increasing the risk of toxicity. In addition, high serum concentrations may take days or weeks to return to the therapeutic or desired range because of phenytoin's long half-life, which is concentration-dependent. Phenytoin is highly protein bound, and free serum concentrations may be needed to properly assess phenytoin concentrations in patients who are critically ill or otherwise hypoalbuminemic. Although correction equations exist to adjust for low albumin, studies have found conflicting results regarding their accuracy in estimating true free concentrations.\textsuperscript{30,31}

**Valproic Acid**
Although less commonly used than phenytoin, valproic acid is another commonly studied second-line anticonvulsant. Valproic acid has shown efficacy comparable with phenytoin in SE.\textsuperscript{32,33} A meta-analysis of benzodiazepine-resistant SE assessed the relative efficacy of anticonvulsants in patients who did not respond to benzodiazepines and found the mean efficacy of valproate to be 75.5% compared with phenytoin (50.2%), levetiracetam (68.5%), and phenobarbital (73.6%).\textsuperscript{34}

Valproic acid has many adverse effects, including hepatotoxicity, pancreatitis, hyperammonemia, and thrombocytopenia, but it lacks the cardiac toxicity associated with phenytoin. It affects the metabolism of other CYP substrates through its inhibition of CYP2C9, resulting in increased concentrations of CYP2C9 substrates. Valproic acid can displace phenytoin from protein binding sites as well as inhibit its hepatic metabolism,\textsuperscript{35} warranting a close follow-up with free serum concentrations of both drugs to optimize efficacy. Several drugs may also affect valproate acid concentrations through interactions not directly related to the CYP hepatic enzymes. Of note, carbapenems can significantly decrease valproic acid concentrations, often making it challenging to reach therapeutic targets. This combination should be avoided whenever possible when treating SE. Valproic acid concentrations should be monitored routinely, particularly at initiation of therapy, with dosage changes, and when interacting drugs are concomitantly used. Free concentrations of phenytoin are more readily available than for valproic acid, which is also known to be highly protein bound. In these cases, it is helpful to assess the serum albumin concentration as well as the free phenytoin to total phenytoin fraction (for patients receiving both agents) to help interpret total valproic acid concentrations. For instance, a patient with low albumin, a subtherapeutic total phenytoin concentration, and a therapeutic free phenytoin concentration may be expected to have a higher free valproic acid concentration (active drug) than generally observed. This may help prevent unnecessary rebolusing and dose escalations for patients with resolving SE in whom dose de-escalation is warranted.
Phenobarbital

Phenobarbital is a barbiturate that exerts an effect by its actions on GABA receptors, but at a different subunit from where benzodiazepines act. In the VA Cooperative Trial, its efficacy was similar to that of lorazepam; however, it is rarely administered as a first-line agent. Its long half-life, drug interactions, and adverse effect profile (i.e., sedation) make it less desirable than the alternatives for urgent control treatment. Accumulation of phenobarbital can occur after repeated doses, making it difficult to assess a patient’s neurological examination, even after doses have been tapered or weaned off completely. Phenobarbital is a reasonable option for patients who require third-line therapy but are not yet eligible for a continuous infusion, such as patients without ventilator support or those who are outside an ICU setting.

Levetiracetam

The use of levetiracetam for SE has grown in recent years because of the availability of an intravenous formulation. It offers advantages over historical agents in being easy to dose (non-weight-based dosing) and free of significant drug interactions. It does not require therapeutic drug concentration monitoring, has very low protein binding, and does not cause respiratory depression. Some laboratories will report drug concentrations for levetiracetam; although a therapeutic range has been recommended, it has not been correlated with therapeutic outcomes in SE. Thus, the role of levetiracetam monitoring is unclear in the general population; however, it may be considered in patients with pharmaco-kinetic alterations such as obesity and continuous renal replacement therapy. In addition, levetiracetam concentrations may be helpful in assessing adherence in patients who were prescribed levetiracetam and present with breakthrough seizures. Levetiracetam can be titrated quickly, and doses higher than those used in chronic epilepsy have been safely used in SE. For these reasons, it has become a staple of urgent control treatment regimens. One study randomized 44 patients with SE to phenytoin intravenously (20 mg/kg)
or levetiracetam intravenously (20 mg/kg) after administration of lorazepam 0.1 mg/kg intravenously. In patients receiving phenytoin versus levetiracetam, there was no difference in clinical termination of seizure activity within 30 minutes (68.2% vs. 59.1%), seizure recurrence within 24 hours (72.7% vs. 59.1%), adverse effects (9.1% vs. 0%), need for mechanical ventilation (27.3% vs. 18.2%), or mortality (9.1% vs. 9.1%). Another study retrospectively compared phenytoin, valproic acid, and levetiracetam as second-line agents for SE. In 167 patients, 198 seizure episodes were identified, and treatment failures were reported in 25%, 41%, and 48% of valproic acid, phenytoin, and levetiracetam patients, respectively (p=0.032 with valproic acid as the comparator). After adjusting for SE severity and etiology, levetiracetam was associated with a higher risk of treatment failure than was valproic acid (OR 2.7; 95% CI, 1.2–6.1), but not phenytoin, and there was no difference in mortality between the three groups. Levetiracetam is not as well studied as phenytoin, valproic acid, and phenobarbital; however, its pharmacokinetic profile makes it an attractive adjunctive agent in the treatment of SE.

Lacosamide

Like with levetiracetam, lacosamide's intravenous availability, ease of dosing, lack of major drug interactions, and well-tolerated adverse effect profile have led to its off-label use in SE. Lacosamide can cause changes on electrocardiogram (ECG) (i.e., PR prolongation), which may warrant ECG monitoring when used at the higher doses for SE, especially in patients with underlying cardiac abnormalities. One analysis of 19 RSE studies of patients treated with lacosamide reported an overall success rate of 56% in 136 cases. Lacosamide was generally well tolerated (dose range 50–600 mg), with sedation being the most common adverse effect (25%) and one patient who developed third-degree atrioventricular block. One study compared two loading-dose regimens of lacosamide in 25 patients with RSE. The overall response rate was 36% for both groups, with a numerically higher overall response in the 400-mg group versus the 200-mg group (50% vs. 18%, p=0.2). The maintenance dose of 200 mg every 12
hours was the same in both groups. The use of lacosamide as an adjunctive treatment for status has also increased during the past few years; however, more data are needed to confirm its place in SE algorithms.

RSE Treatment

Status epilepticus that is unresponsive to first-line (emergent) or second-line (urgent) therapies is considered RSE. Treatment of RSE uses anesthetics and continuous intravenous infusions. The results of studies evaluating these treatment modalities are difficult to interpret, partly because of the heterogeneous patient populations, non-standardized treatment regimens, and variable dosing strategies. Given the lack of superiority data establishing a standard of care, patient-specific characteristics, such as hemodynamic stability as well as physician preference and institutional algorithms, generally guide agent selection. Continuous infusions may be implemented as refractory treatment, after failure of initial anticonvulsants, or earlier to allow the traditional anticonvulsants enough time to be initiated and to reach therapeutic concentrations. When continuous infusions are titrated, they should be rebolused with every increase in the continuous infusion rate. Commonly, 24–48 hours of seizure control is recommended before continuous infusions and drugs are tapered; however, practices varies widely among clinicians, particularly in super-refractory status epilepticus treatment. Several anticonvulsants may be used adjunctively, particularly when trying to wean off the anesthetic infusions.

Propofol

Propofol is a very short-acting anesthetic that acts on GABA receptors and may have an effect on NMDA receptors. It causes significant hypotension at treatment doses for SE, which are often higher than that required for continuous sedation, necessitating the use of vasopressors. The risk of propofol-related infusion syndrome (PRIS) associated with higher doses and long durations of propofol makes it
less ideal for treatment of RSE, where high doses are often needed for extended periods. Triglycerides (TG) should be evaluated every 48–72 hours in patients receiving propofol, with TG concentrations greater than 400 mg/dL necessitating a potential dose reduction, discontinuation, or change to alternative therapy. One prospective, randomized study of 23 patients with RSE randomized patients to barbiturates (pentobarbital 5-mg/kg bolus and thiopental 2-mg/kg bolus) or propofol (2 mg/kg bolus) titrated to burst suppression. The median doses for each agent were propofol 5.5 mg/kg/hour (range 2–10.9), thiopental 7 mg/kg/hour (range 4–20), and pentobarbital 2.5 mg/kg/hour (range 2–3). Investigators of this study found no difference in mortality between propofol and barbiturates, but they did find a longer duration of mechanical ventilation with barbiturates and a nonsignificant increase in RSE control with propofol (43% vs. 22%). One patient in the propofol group was determined to have PRIS.41

Midazolam Continuous Infusion

Continuous infusion midazolam is the benzodiazepine of choice for RSE treatment because of its lack of propylene glycol diluent, which allows it to be administered at high doses for long durations without risk of toxicity and metabolic acidosis. Midazolam is a CYP3A4 substrate and is affected by CYP3A4 inducers and inhibitors (including other concomitantly used anticonvulsants). Although the parent drug undergoes hepatic metabolism, it has an active metabolite that is renally eliminated; thus, its half-life is prolonged in older adult patients or those with renal failure. After prolonged infusions, midazolam distributes into adipose tissues and can prolong sedative effects. Midazolam causes respiratory depression requiring intubation, and high doses often cause hypotension requiring vasopressors, although generally less so than propofol. A retrospective study of 20 patients found no difference in clinical seizure suppression (64% vs. 67%) or electrographic seizure suppression (78 vs. 67%) between propofol and midazolam, respectively, as well as no difference in infection, duration of mechanical ventilation, or hemodynamic compromise. Mortality was nonsignificantly higher in the propofol group (57% vs. 17%), although
patients receiving propofol had a longer duration of SE before treatment. Propofol was administered as a bolus (1–3 mg/kg) in some, but not all, patients, followed by a continuous infusion range of 1–10 mg/kg/hour. Midazolam was administered as a bolus (2–12 mg) and continuous infusion of 0.05–0.8 mg/kg/hour. Another study identified 33 patients with continuous EEG monitoring who received midazolam (0.1- to 0.2-mg/kg bolus, followed by an infusion at 0.05–0.4 mg/kg/hour) for RSE. Seizure termination was seen within the first hour in 82% of patients, and breakthrough seizures were seen in 56% of patients who were treated for more than 6 hours. Midazolam did not control RSE in 18% of cases and required switching to an alternative continuous infusion anesthetic.

**Pentobarbital**

Pentobarbital is a long-acting barbiturate that can be used in place of propofol or midazolam for RSE. Pentobarbital is known to cause significant cardiovascular depression and hypotension, leading to cardiovascular collapse and the requirement of vasopressors in order to maintain therapeutic infusion rates. Mechanical ventilation is required before initiation due to respiratory depression. Pentobarbital has a half-life of 15–48 hours, but it may take days to weeks for complete elimination. Its long half-life complicates neurological examinations and prognostication. For patients evaluated for brain death, pentobarbital may confound the examination, and serum concentrations typically come back elevated for significant periods after the drug has been discontinued. In addition, adverse effects are noted even after the infusion has been discontinued, leading to possible prolonged mechanical ventilation and hypotension, higher risk of infections, and reduced gastrointestinal motility. One systematic review that assessed pentobarbital, propofol, and midazolam for the treatment of RSE in 193 patients and 28 studies found no difference in mortality between the three treatments. Pento-barbital was associated with less short-term treatment failure and fewer breakthrough seizures than the other agents; however, fewer patients received cEEG monitoring than in the propofol and midazolam groups, making it possible to have missed
some breakthrough seizures. Pentobarbital was more frequently titrated to burst suppression rather than seizure termination, and titration to EEG suppression was associated with fewer breakthrough seizures (4 vs. 53%, p<0.001) regardless of treatment arm. However, most of the patients treated to a goal of EEG burst suppression were in the pentobarbital group, making it difficult to draw conclusions on efficacy from these results. Moreover, the maximum infusion rate of midazolam (0.23 mg/kg/hour) was much lower than that recommended in the current guidelines.\(^3\) Pentobarbital was associated with more hypotension requiring vasopressors than were propofol and midazolam (77% vs. 42% and 30%, p<0.001).\(^4\) Another review of 31 patients treated with pentobarbital (10–15 mg/kg loading dose and continuous infusion of 0.5–4 mg/kg/hour) for RSE found a 90% control rate but a 48% recurrence rate while weaning the continuous infusion, even in patients who had achieved burst suppression. Complications surrounding pentobarbital exposure included pneumonia (32%), hypotension requiring vasopressors (32%), urinary tract infections (13%), deep venous thromboses (10%), and ileus (10%).\(^5\)

**Ketamine**

Ketamine is a NMDA receptor antagonist that may be beneficial in RSE when changes in GABA receptor affinity and regulation may be altered. Although all the other continuous infusions used for RSE cause hypotension, ketamine has a stable hemodynamic profile, sometimes even resulting in elevated blood pressure, which may be desirable when used with other agents that may cause hypotension. Because ketamine may increase intracranial pressure, it should be used cautiously when intracranial hypertension is present or suspected. In one retrospective review of 11 patients with RSE, ketamine was added to a continuous infusion anesthetic.\(^6\) Patients received boluses of 1–2 mg/kg and were initiated on weight-based infusions of 0.45–2.1 mg/kg/hour (7.5–35 mcg/kg/minute). All patients had resolution of RSE, and 73% of patients were able to have the concomitant anesthetic infusion weaned off within 72 hours. Six of seven patients (85%) who required hemodynamic support were able to be weaned off
vasopressors after ketamine initiation. In another study, 60 patients with RSE received ketamine as add-on therapy, administered as a bolus dose (median 1.5 mg/kg, maximum 5 mg/kg) and continuous infusion (median 2.75 mg/kg/hour [46 mcg/kg/minute], maximum 10 mg/kg/hour [167 mcg/kg/minute]). Fifty-seven percent of patients achieved permanent RSE control. Ketamine is an attractive treatment option in RSE; however, current data support its use when initiated as an adjunctive continuous infusion, followed by slow titration of other continuous infusions.

**Topiramate**

Topiramate is an oral agent used in the management of chronic epilepsy. It is a sodium channel blocker, but it also causes enhanced effects of GABA and glutamate inhibition at AMPA/kainate receptors. Because topiramate’s effects on GABA are independent of the GABAa receptor, it may theoretically help when benzodiazepine resistance is suspected in later stages of SE. Its inhibitory effects on glutamate transmission also provide an added mechanism of action in SE treatment and make it a useful adjunctive agent. In one case series, six patients who received topiramate (300–1600 mg) in addition to their treatment regimens for RSE had resolution of seizure activity and were discharged from the hospital. The main disadvantage of topiramate is its lack of an intravenous formulation. For this reason, it is generally reserved as adjunctive therapy after more rapid intravenous therapies have been initiated. It is also a weak carbonic anhydrase inhibitor and can cause metabolic acidosis when used at high doses. Topiramate may be useful when patients are weaned off interacting drugs or when the adverse effect profile is unacceptable (e.g., increasing liver function tests). When used in SE, the dose should be rapidly titrated to a maximum of 1600 mg/day in divided doses.

**Inhaled Anesthetics**

Efficacy with the inhaled anesthetics isoflurane and desflurane for the treatment of RSE has been reported in case reports or case series as
an adjunct to conventional SE treatment (a combination of benzodiazepines, barbiturates, and anticonvulsants). Their use may be associated with cognitive changes, sedation, and hypotension; however, their rapid onset and elimination allow for easy titration if the adverse effects become unmanageable. Administration of inhaled anesthetics may be technically difficult because of unfamiliarity with the dosing and administration outside the operating room setting. In addition, monitoring of these agents without appropriately trained providers may be logistically challenging and require institution-specific protocols to do so safely within the ICU. Availability of an end-tidal anesthetic monitor may delay the initiation of inhaled anesthetics and offset the benefits of their rapid onset of activity.\textsuperscript{49-51}

**Nonpharmacologic Treatment**

In addition to the available treatment options, nonpharmacologic strategies including the ketogenic diet, vagal nerve stimulation, electroconvulsant therapy, induced hypothermia, and surgical management have been evaluated; however, there is insufficient evidence to support their routine use. These strategies are best used as an adjunct to drug therapy, if at all. Correction and identification of an underlying cause such as hypoglycemia and alcohol withdrawal seizures is critical and may lead to different treatment algorithms. Induced hypothermia is the most common nonpharmacologic treatment management used in the ICU setting, although robust studies are lacking. In one case series of four patients with RSE, the addition of therapeutic hypothermia (TH) (31°C–35°C) resulted in seizure cessation in all four patients and burst suppression in three.\textsuperscript{52}

Special consideration should be given to drug dosing in patients undergoing TH because of alterations seen in metabolism and volume of distribution of agents used in SE. The metabolism of propofol decreases in TH, increasing the risk of toxicity with normally used doses.\textsuperscript{53} Clinicians should consider close titration of propofol using EEG monitoring for patients undergoing TH. Midazolam does not seem to be affected by TH.\textsuperscript{54} Phenytoin metabolism is decreased in TH by
about 70% in mild TH, but specific dosing guidelines have not been published. It is probably most prudent to dose by free serum concentrations in this situation.

### Treatment Considerations

Given the lack of randomized controlled trials comparing various treatment options, the treatment of SE has become prescriber-, institution-, and patient-specific. Potential considerations when selecting pharmacotherapy treatments include cost, availability of an intravenous formulation, adverse effect profile, hospital formulary options, and drug shortages. Additional unanswered questions surrounding continuous infusions include the timing of titrations, most appropriate titration dosing strategy, and duration of continuous infusions. Once the decision has been made to transition from a continuous infusion to intermittent therapy, clinicians should determine which anticonvulsants to continue, discontinue, or dose adjust. Often, many anticonvulsants are added almost simultaneously, but the continuation of five or six agents after seizure termination is unnecessary and may contribute to added adverse effects and potential drug interactions. Continuous infusions may be necessary in the treatment of RSE, but the preferred agents and duration of treatment are unknown. Several studies have shown that outcome is not influenced by the choice of continuous infusion.\(^{41,42,56}\) A worse outcome, including increased mortality, infections, and length of stay, has also been documented in patients managed with therapeutic coma; however, these are all retrospective in nature and subject to possible selection bias of sicker patients.\(^{56-58}\) Once continuous infusions have been weaned off (or, in many cases, while they are still being administered), de-escalation of therapy and transition from intravenous to oral therapy can occur during cEEG monitoring. Commonly, 24–48 hours of seizure control is recommended before tapering of continuous infusions and drugs.\(^3\) There are no established guidelines on weaning off continuous infusions; however, considerations include duration the patient was on the infusion, half-life of the infused drug, and the
patient’s renal and hepatic function. For example, an older adult patient with compromised renal function who has received continuous infusion midazolam for several days can be weaned faster than can a younger patient with good renal function receiving only 1 day of therapy because the active metabolite has not had the opportunity to accumulate. There is also no consensus regarding the optimal treatment duration, the precise tapering mechanism, or the total number of maintenance anticonvulsants for patients whose seizures resolve. These decisions, as well as when to consider alternative or salvage therapy, are often left to the discretion of the treating physician or neuro-ICU team. Algorithms are provided for initial SE treatment (Figure 19.3) and RSE treatment (Figure 19.4) that include many of the previously mentioned therapeutic considerations as well as expert opinion and clinical experience.

**MONITORING**

**Electroencephalography**

Continuous EEG monitoring is recommended for all patients with active SE and should be reviewed often throughout the day.\(^3,23\) Because NCSE may be intermittent, spot (e.g., 6 hours) EEG monitoring is often inadequate and may miss more than 50% of the seizure episodes that are subsequently captured in cEEG.\(^59\) The target goal for dose titrations with EEG monitoring remains controversial, with some clinicians treating toward cEEG burst suppression patterns and others treating toward seizure termination.\(^3,23,28,60\) One systematic review showed fewer breakthrough seizures (53% vs. 4%, \(p<0.001\)) and more hypotension (76% vs. 29%, \(p<0.001\)), but no difference in treatment failure or withdrawal seizures, with a goal of EEG burst suppression compared with seizure suppression.\(^44\) Data regarding the duration of cEEG are lacking. After termination of seizures, the decision of when to discontinue continuous monitoring and use spot EEGs is left to the discretion of the clinician, often dependent on concomitant therapy and duration of SE.\(^3,60,61\) Surveys of neurologists, neurophysiologists, and
neurointensivists reported that 47%–50% would continue cEEG for 24 hours after non-convulsive seizure termination. Current guidelines recommend cEEG for 24 hours after seizure termination on EEG or during anticonvulsant weaning trials and 48 hours for comatose patients. In general, more stable patients who have been weaned off continuous infusions are considered for discontinuations of cEEG.

**Laboratory**

Several anticonvulsants that can be measured in the serum have known target drug concentration ranges that correlate with efficacy. These drugs include phenytoin and fosphenytoin (phenytoin concentrations assessed), valproic acid, phenobarbital, and carbamazepine. Weight-based loading doses should achieve target concentrations in most patients; however, in patients where pharmacokinetic variables are assumed to be altered (e.g., traumatic brain injury patients), post-load concentrations (2 hours after a dose) can be obtained to ensure adequate therapeutic concentrations for individual patients. Monitoring trough anticonvulsant concentrations about 24 hours after the loading dose and then 48 hours later may be reasonable to ensure continued therapeutic targets. Although therapeutic ranges exist for chronic treatment of epilepsy, clinicians often target the higher end of these ranges during the treatment of SE and sometimes concentrations above the therapeutic range. In these cases, the benefit of more aggressive seizure management is deemed to outweigh the low risk of acute drug toxicities. Free trough concentrations should be checked whenever possible; however, proper knowledge of institutional protocols and turnaround time is important because in-house assays for free concentrations are not always available and may take longer to obtain results. Where drug concentration monitoring is not available, especially for many of the newer anticonvulsants, monitoring renal function may help guide dosing adjustments in renally eliminated drugs, and monitoring for toxicity will help determine dose reductions or the need to switch to an alternative drug. Baseline laboratory values including a basic metabolic panel, toxicology screen, and blood gas are
also helpful and should be ordered according to the individual patient and clinical scenario. Liver function tests should be ordered at baseline and about every 72 hours in patients receiving phenytoin, fosphenytoin, or valproic acid or more often for patients having liver function test elevations or receiving other hepatotoxic drugs.

Figure 19.3 Initial treatment of status epilepticus.

SPECIAL POPULATIONS

Children

The approach to the treatment of SE in critically ill children is similar to that in adults, and various guidelines have been published for pediatric SE.\(^{63}\) Special consideration must be made for increased hepatic metabolism seen in pediatric patients\(^{64}\) as well as for difficulties in obtaining intravenous access. The use of buccal,\(^{65}\) nasal,\(^{66}\) rectal,\(^{67}\) intramuscular,\(^{68}\) and intraosseous routes has been published in children.
Refactory Status Epilepticus  
(Failure of benzodiazepine and first AED)

Patient intubated?

No

1. Add second AED*
   Phenytoin OR
   Fosphenytoin OR
   Valproic acid
   *Select a different AED from initial treatment; optimize the first AED (e.g., obtain level, re-bolus if needed)

   Intubate

Yes

1. Start continuous infusion*
   Midazolam OR
   Propofol
   *Can add second AED concomitantly; optimize current AEDs

2. Change continuous infusion*
   Midazolam OR
   Propofol
   *Switch to a different CI
   *Can add additional AEDs concomitantly; optimize current AEDs

3. Add continuous infusion*
   Ketamine OR
   Pentobarbital
   *May wean off previous CI if goal seizure suppression/EEG suppression achieved

4. May consider one or more of the following* 
   Optimize and/or add additional AEDs
   Inhaled anesthetics
   Nonpharmacologic options (therapeutic hypothermia, ketogenic diet, vagal nerve stimulation, electroconvulsant therapy, surgery)
   Treat suspected, yet still undiagnosed underlying cause that has not yet been treated

*All AEDs should be reviewed, goals of care discussed, consideration for futility of pharmacotherapy
Older Adults

The proportion of older adult patients admitted to the ICU has increased during the past several years and, unfortunately, so has the mortality in this patient population, even after controlling for underlying comorbidities. Older adult patients have a higher incidence of SE and a higher mortality rate than do younger patients. Mortality rates approach 50% in patients older than 80 years who have generalized convulsive SE; lower rates of 30% were reported for patients with partial SE. Stroke is a major cause of SE in older adults and is associated with 60% of cases; other common causes include trauma, anoxia, metabolic disturbances, and subtherapeutic anticonvulsant concentrations. Anoxic brain injury incurs the poorest prognosis, with almost complete fatality (70%–100%). Because signs and symptoms in the older adult critically ill patient may be difficult to observe, cEEG is recommended for timely diagnosis and treatment, especially when NCSE is suspected. Partial SE is more common in the older adult than are generalized tonic-clonic types, and signs may be as subtle as confusion, atypical behavior, or depressed consciousness. In one study, it was reported that about 16% of patients with un-provoked confusion were actually in NCSE. Another study examining older adult patients with delirium had EEG findings consistent with NCSE in about 28% of patients. Sedation and narcotic use, which are common treatments in the ICU, may mask these signs and potentially delay treatment.

Treatment of SE in the older adult generally follows contemporary management, despite the lack of representation in the few randomized clinical trials in SE to date. This patient population requires special attention to drug dosing because of decreased volume of distribution,
decreased protein binding, decreased renal and hepatic function, and potential for drug interactions because of polypharmacy. To minimize adverse effects in the older adult, accurate weights should be used to calculate doses, and doses should be individualized. Electrocardiogram and blood pressure should be monitored closely, especially with parenteral agents containing propylene glycol because hypotension and arrhythmias are common. Infusion rates should be decreased when necessary, especially in patients with tenuous or unstable cardiac conditions. Older adult patients are particularly sensitive to the respiratory depressant effects of barbiturates, so consideration for intubation should be made before intravenous administration. Valproic acid is an attractive agent to use in the older adult because of its low risk of hypotension, respiratory depression, and sedation compared with other agents. Levetiracetam is also attractive for the same reasons but has the additional benefit of minimal drug interactions. No published studies show the superiority of one agent over another. Therapeutic drug monitoring, when appropriate, is essential to minimize toxicity, especially when concomitant renal and hepatic dysfunction exists.

Pregnancy

Very little has been published regarding SE in pregnancy, especially in patients being treated in an ICU. In a prospective registry of pregnant women with epilepsy, SE was reported in 0.6% of all pregnancies (0.3% were categorized as convulsive). No maternal or fetal deaths were attributed to SE in this series. Uncontrolled seizures could theoretically compromise fetal blood pressure, heart rate, and oxygenation and be associated with poor postnatal cognitive development. No data are available regarding the mortality of SE in pregnancy. Seizure control in women with epilepsy requires adherence to anticonvulsant therapy because withdrawal can lead to SE and subsequent complications. Consideration must be given to addressing the changes in pharmacokinetics seen during pregnancy and making appropriate adjustments in therapy.
The acute treatment of SE in pregnancy follows general guidelines because the priority is control of both physiological and electrical manifestations in order to minimize adverse effects on the mother and fetus. Although many of the anticonvulsants used in SE have associated teratogenicity, there is no evidence to suggest that limited, acute treatment leads to any fetal complications. If the source of the provoked seizures can be identified and treated, there may be no need to initiate anticonvulsant therapy. Input from neurology and obstetrical services is important in the intensive care management of these patients (enrollment in an antiepileptic drug pregnancy registry may be recommended). Drug dosing can be challenging in this population because various pharmacokinetic parameters change during pregnancy: the volume of distribution increases and protein binding decreases because of increases in weight and a decline in albumin production, respectively.\(^{77}\) In addition to SE, any underlying critical illness must be addressed and treated.

**Obesity**

Drug dosing can be challenging in critically ill patients with obesity, and there are limited recommendations for drugs used in SE. Changes in volume of distribution typically affect loading doses of drugs while having minimal impact on maintenance regimens. Of the anticonvulsants, only phenytoin/fosphenytoin and phenobarbital have specific dosing recommendations in obesity.\(^{78,79}\) A dosing weight (DW) for phenytoin can be calculated from ideal body weight (IBW) and actual body weight (ABW) using the following calculation: $\text{DW} = \text{IBW} + 1.33(\text{ABW} - \text{IBW})$. This dosing weight can then be used to calculate a volume of distribution ($\text{Vd}$): $\text{Vd} = 0.7 \text{ L/kg}$. Finally, a loading dose (LD) can be estimated: $\text{LD} = \text{C}_{\text{target}} \times \text{Vd}$, where $\text{C}_{\text{target}}$ is the goal serum concentration (typically 15–20 mg/L). Intravenous doses of phenobarbital can be dosed using total body weight.\(^{79}\) Some institutions may cap loading doses for patients with obesity as a safety precaution; extremely large loading doses may be divided into smaller doses given sequentially, using post-load concentration monitoring,
Renal/Hepatic Failure

Renal and hepatic dysfunction are common conditions encountered in ICU patients. Most cases of SE in renal failure stem from drug toxicity caused by impaired clearance. Particularly notable are antibiotics, especially penicillins and β-lactams. Fluoroquinolones are also implicated in drug-induced seizures and SE. These patients typically respond to benzodiazepines and anticonvulsants, although once the suspected offending agent is discontinued or dose adjusted, long-term prophylactic therapy is probably unwarranted.

Patients with renal failure who are receiving continuous renal replacement therapy deserve special consideration. For some anticonvulsants, drug clearance may increase above normal ranges during some modes of continuous renal replacement therapy such as continuous venovenous hemofiltration, requiring more frequent dosing than expected. Because of the changes in protein binding and volume of distribution seen in patients with renal failure, the free fraction of highly bound drugs may be altered, and free serum concentrations of anticonvulsants should be measured to ensure appropriate clinical response.

Liver dysfunction can be prevalent in the ICU and can complicate drug selection in SE. Drugs that are not hepatically metabolized to active metabolites or hepatotoxic moieties are preferred agents to use in SE. Lorazepam, levetiracetam, and lacosamide are attractive agents from this standpoint. Hepatic encephalopathy can confound the presence of SE in patients with cirrhosis, and lactulose has been reported to be effective in rare cases. Patients with encephalopathy may need continuous EEG monitoring to help identify the onset or presence of seizures.

Genetics

Very little has been reported on genetic considerations in SE or
treatment of SE. Although there appear to be differences among ethnicities with respect to incidence of SE and mortality, there is no genetic test to predict the risk of SE in the general population. Genomic testing is available for certain anticonvulsants, but only to decrease the risk of serious and potentially fatal dermatologic adverse effects. Patients with the HLA-B*1502 allele may be predisposed to the development of Stevens-Johnson syndrome or toxic epidermal necrolysis when administered phenytoin or lamotrigine.92 The use of genetic screening in the setting of a patient with SE is unclear. Critically ill patients with a history of the HLA-B*1502 allele should not be given phenytoin or fosphenytoin in the setting of SE.

CONCLUSIONS AND FUTURE AREAS OF DEVELOPMENT

Many options are available in the treatment armamentarium for SE; however, robust comparison data are lacking. Specifically, no prospective, randomized trials directly compare second- and third-line agents added to a standardized treatment regimen. There are also a paucity of randomized controlled trials assessing the role of newer agents in the treatment of SE. Finally, there is little guidance on the role of continuous infusions early on in status management compared with the addition or dose escalation of more anti-convulsants. This leaves agent selection to a combination of institution-specific treatment algorithms and clinician experience and preference. Future studies should use standardized protocols to evaluate the addition of second-, third-, and fourth-line treatment strategies against a consistent background of therapy. Doses as well as drug concentrations at the time of seizure cessation should be reported. Reasons for drug discontinuation should be clearly described. Goals for weaning of continuous infusions should be provided, as well as the specific weaning strategy, parameters for tapering the continuous infusion, and cEEG titration goals (burst suppression vs. seizure termination). Pharmacoeconomic studies should evaluate different treatment strategies, considering overall patient outcomes as well as cost of
newer drugs, need for drug concentration monitoring, and duration of mechanical ventilation with continuous infusions. Studies should also clearly define their patient populations and aim to identify subgroups of patients or specific characteristics that may predict better response. Added resources such as faster cEEG interpretation, improved turnaround time on drug concentration assays, and earlier identification of patients in SE may shorten the time to treatment initiation and escalation.

LEARNING OBJECTIVES

1. Discuss the epidemiology and pathophysiology of traumatic brain injury (TBI) and acute spinal cord injury (SCI).

2. Compare various treatment options for elevated intracranial pressure.

3. Choose the most appropriate pharmacotherapy for TBI and acute SCI.

4. Describe current investigational pharmacotherapies for TBI and acute SCI.

ASIA  American Spinal Injury Association
BTF  Brain Trauma Foundation
CNS  Congress of Neurological Surgeons
Traumatic brain injury (TBI) is a medical condition that can have devastating effects on patients and families. Traditionally, the severity of TBI has been classified using the Glasgow Coma Scale (GCS). However, sedatives, neuro-muscular blocking agents, and intubation can potentially decrease the GCS thereby, increasing the severity classification of TBI.¹ This limitation has led to the development of other coma scales such as the Full Outline of Unresponsiveness (FOUR) score.² Unlike the GCS, the FOUR score allows for assessment of brain stem function and responsiveness in patients unable to speak (Table 20.1). When used to classify the severity of TBI, the goal of these coma scales is to correlate a potentially poor outcome (e.g., death, disability) with the scale score. Patients who have the highest potential for a poor outcome and require critical care can be classified as having severe TBI (GCS 3–8). Although the mortality associated with severe TBI has declined, a recent report suggested a mortality of 14.1% in patients who sustained a severe TBI while involved in a motor vehicle collision.³,⁴ Mortality that is associated
with severe TBI is multifactorial. Compared with those who lived in high-income countries, patients with severe TBI who live in low- and middle-income countries had a higher chance of death. In addition, patients with a systolic blood pressure higher or lower than 120–140 mm Hg on admission may have a higher probability of death. Increasing age, prehospital hypoxemia (Spo$_2$ [peripheral capillary oxygen saturation] less than 90%), and prehospital hypothermia (temperature less than 35°C) may be risk factors for increased mortality as well.

The pathophysiology of severe TBI can be broadly categorized as primary and secondary injury. Primary injury occurs during the initial trauma as energy is transferred to the brain and surrounding central nervous system tissues. The initial impact can cause shearing of axons, contusions, swelling, and dysregulation of blood flow leading to ischemia. Secondary brain injury is a complex disease state that can begin minutes to hours to days after the initial injury. Soon after the initial injury, the brain is inundated with high levels of excitatory neurotransmitters. The primary excitatory neurotransmitter in this setting, glutamate, binds to NMDA (N-methyl-d-aspartate) receptors and AMPA ($\alpha$-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors, causing an influx of calcium into the cells. Ultimately, this excess of excitatory neurotransmitters leads to cell damage, necrosis, and apoptosis. In addition, the blood-brain barrier is disrupted during the primary injury, allowing an influx of peripheral immune cells and cytokines into the brain parenchyma. Neutrophils from the peripheral blood driven by increases in local iNOS (inducible nitric oxide synthase), COX-2 (cyclooxygenase-2), NADPH (nicotinamide adenine di-nucleotide phosphate), and other cytokines increase oxidative activity. This further damages the brain parenchyma and degrades the blood-brain barrier. Activation of the brain microglia and astrocytes by cellular debris and cytokines increases the production of many proinflammatory markers (interleukin [IL]-1$\beta$, IL-6, tumor necrosis factor alpha) and anti-inflammatory markers (IL-10, transforming growth factor beta). These pro- and anti-inflammatory markers have a very complex role in the pathophysiology of severe TBI. Studies have
not consistently found a correlation of increased pro- and anti-inflammatory markers with poor outcomes. In part, this contradiction in patient outcome and inflammatory markers may be the result of differences in sampling time and fluid type sampled (i.e., cerebrospinal fluid vs. peripheral blood vs. extracellular fluid). Edema secondary to the primary injury and increased inflammatory markers increases the intracranial pressure (ICP). This further decreases cerebral blood flow, which in turn leads to further cerebral ischemia and cell death.

The mechanisms of secondary injury after severe TBI offer many potential therapeutic targets for improving the clinical outcomes of patients who have experienced severe TBI. In 2007, the Brain Trauma Foundation (BTF) revised its treatment guidelines for the management of severe TBI. These are the most authoritative recommendations for the treatment of these patients. Where appropriate, levels of evidence from the BTF severe TBI guidelines will be cited. Treatment algorithms for TBI can be found in Figures 20.1 and 20.2.

| Table 20.1 | Glasgow Coma Scale Score and FOUR Score Comparison |
## ICP Control

### Hyperventilation

Hyperventilation and the induction of hypocapnia (Paco$_2$ less than 35 mm Hg) results in cerebral vasoconstriction and decreased blood flow.
to the brain. At the price of reduced cerebral blood flow, decreased oxygen delivery to the brain, and ischemia, ICP is quickly reduced.\textsuperscript{12} Prolonged use of this therapy is related to worse outcomes at 3 and 6 months after injury\textsuperscript{13} and may be associated with increased mortality and when overused before hospital arrival. Dumont et al. retrospectively evaluated patients with TBI and grouped them according to their presenting Paco\textsubscript{2}. The authors found that compared with normocapnic patients, those with a Paco\textsubscript{2} less than 35 mm Hg had increased mortality (77\% vs. 15\%).\textsuperscript{14} The BTF guidelines give level II evidence that recommends against the use of prophylactic hyperventilation and level III recommendations that hyperventilation should only be used as a “temporizing measure for the reduction of elevated intracranial pressure” and that “hyperventilation should be avoided during the first 24 hours after injury.”\textsuperscript{15}
Patient with severe brain injury (GCS < 8)

1. Immobilize spine
   Intubate, oxygenate
   Head of bed 30 degrees
   Obtain ABGs, CBC, chemistries, EtOH Cp, toxology screen

2. SBP < 90 mm Hg

**Hyperosmolar Therapy**

The two primary agents used for hyperosmotic therapy to control ICP are mannitol and hypertonic saline. Mannitol is a sugar alcohol that is usually prepared for intravenous administration as a 20%–25% solution. Mannitol can be administered by a central venous catheter or a peripheral venous catheter. Mannitol affects the cerebral blood flow and ICP though two primary mechanisms of action. Immediately after infusion of mannitol, blood viscosity is decreased, thus increasing cerebral blood flow throughout the brain. When autoregulation is intact, this increase in cerebral blood flow causes a compensatory vasoconstriction and rapid reduction in ICP. The osmotic effect of mannitol occurs about 15 minutes after infusion. Mannitol causes a dehydration of brain tissue and hyperosmolarity through diuresis. This in turn decreases ICP.16-18 Because mannitol is a strong osmotic diuretic, significant hypotension and significant fluid shifts can occur after administration. These rapid fluid shifts may be detrimental to patients with significant comorbidities (e.g., heart failure). Although the mechanism is not fully elucidated, mannitol can cause renal insufficiency in the setting of extreme hyperosmolarity. The dogmatic approach has been to discontinue or limit mannitol once the serum osmolarity reaches 320 mOsm; however, in clinical practice, this value is routinely exceeded. Acute renal insufficiency associated with mannitol may be related to accumulating mannitol plasma concentrations and cumulative mannitol dose.19 The serum osmole gap, calculated as (measured osmolarity – calculated osmolarity), correlates with accumulating plasma concentrations better than serum osmolarity.20 Compared with serum osmolarity, the serum osmole gap may be a better monitor for mannitol toxicity. Literature suggests that
maintaining a serum osmole gap of less than 55 reduces the risk of renal insufficiency\textsuperscript{21,22}; however, many practitioners conservatively target an osmolar gap of less than 18–20. In addition, mannitol is renally eliminated. Thus, in patients with significant renal insufficiency, mannitol may accumulate, necessitating a change in treatment agent. Hypertonic saline, usually prepared in concentrations of 1.5\%–23.4\%, must be administered by a central venous catheter when concentrations are greater than 3\%. It decreases ICP by directly causing hyperosmolarity. This effectively dehydrates brain tissue, thus decreasing ICP. Hypertonic saline has been administered as a bolus or continuous infusion. The bolus dose varies depending on the concentration of sodium chloride; however, the osmolarity of the dose administered should be comparable with that of a therapeutic mannitol dose.\textsuperscript{23} Table 20.2 contains equimolar doses of mannitol and hypertonic saline. Unlike mannitol, hypertonic saline does not cause diuresis and will expand the intravascular volume. Consequently, care should be taken when using hypertonic saline in patients when expanded intravascular volume would be deleterious (e.g., patients with heart failure). In addition, there is concern for osmotic demyelinating syndrome when using hypertonic saline in patients with chronic hyponatremia. Therefore, in patients with chronic hyponatremia, hypertonic saline therapy for increased ICP should be avoided.\textsuperscript{24}

The BTF guidelines only give recommendations for the use of mannitol to control intracranial hypertension. They state that “mannitol is effective for control of raised ICP at doses of 0.25 gm/kg to 1 g/kg body weight. Arterial hypo-tension (systolic blood pressure less than 90 mm Hg) should be avoided (level II evidence).”\textsuperscript{24} Since those guidelines were published in 2007, a significant amount of data comparing hypertonic saline and mannitol for the control of ICP have been published. A 2011 meta-analysis by Kamel et al. evaluated five trials that compared equimolar doses of mannitol and hypertonic saline. The authors found that patients treated with hypertonic saline had a better risk of achieving ICP control (relative risk [RR] 1.16; 95\% confidence interval [CI], 1.00–1.13).\textsuperscript{25} A second meta-analysis from 2012 found 12 studies that compared hypertonic saline with mannitol.
Of those, nine found hypertonic saline superior to mannitol for reduction of ICP. Eight studies compared hypertonic saline and mannitol with respect to treatment failure or insufficient ICP reduction. Compared with patients treated with mannitol, significantly fewer patients had treatment failure or insufficiency when treated with hypertonic saline (odds ratio 0.36; 95% CI, 0.19–0.68). This meta-analysis compared non-equimolar doses of agents; thus, it may overestimate the treatment effect of hypertonic saline. However, because the results are similar to those of previous meta-analyses, the trend of less treatment failure with hypertonic saline remains.

Choice of the most appropriate hyperosmolar therapy to decrease ICP must be linked not only to efficacy but also to speed of agent availability, access for administration (i.e., central vs. peripheral catheter), and patient-specific considerations (e.g., volume status, presence of hyponatremia, renal dysfunction). Therefore, a single approach cannot be taken with these agents. Although data suggest that hypertonic saline is more effective at reducing ICP, mannitol remains a useful agent.

Barbiturate Therapy
Compared with hyperosmotic therapy, barbiturates are not as effective at reducing ICP. However, barbiturates may have a role in control of refractory ICP. The BTF guidelines give level II evidence for the use of barbiturates “to control elevated ICP refractory to maximum standard medical and surgical treatment.” Many barbiturate regimens have been used, but most commonly, medications are titrated to induce and maintain electroencephalographic burst suppression. There is little correlation between barbiturate plasma concentrations and achievement of electroencephalographic burst suppression; thus, barbiturate plasma concentrations should not be used to monitor the efficacy of a treatment regimen. Table 20.3 lists the most commonly used barbiturate regimens. A 2012 meta-analysis evaluated the effect of barbiturate coma and found no effect on outcome. In addition, the investigators found a significant risk of hypotension associated with the use of barbiturate coma, which may decrease this treatment’s clinical significance. A prospective cohort of five European countries was used to evaluate the use of barbiturates in patients with TBI. Compared with the time before barbiturate administration, patients who received high-dose barbiturates had a significant reduction in time with ICP greater than 25 mm Hg (6.4 hours ± 7.05 hours vs. 4.2 hours ± 5.9 hours; p<0.05), but they also had more time with a mean arterial pressure less than 70 mm Hg (6.2 hours ± 6.1 hours vs. 9.4 hours ± 8.2 hours; p<0.05). When survival was adjusted for age, GCS score, and injury severity score, no mortality benefit was associated with high-dose barbiturates.

Although barbiturate coma may play a role in management of refractory ICP management, data are sparse suggesting this therapy will benefit long-term clinical outcomes. Currently, these agents should be considered only if all other efforts to control ICP have been exhausted. Close monitoring for, and management of, hypotension should be employed when using these agents for the treatment of elevated ICP.

**Neuromuscular Blockade**

The role of neuromuscular blockade (NMB) is not clearly defined in
patients with severe TBI. However, it is often considered for control of ICP. The potential advantages of NMB include prevention of ventilator dyssynchrony, prevention of coughing during stimulating procedures (e.g., endotracheal suctioning), prevention of shivering during targeted temperature management, and decreased metabolic demand. All of these potential advantages decrease the ICP or decrease metabolic demand.

The literature surrounding these advantages is less clear. A 2015 systematic review identified 32 articles related to this topic. The data were too diverse to perform a meta-analysis, and there was no consistent theme of benefit or harm. The authors concluded that if NMB was considered in the treatment of severe TBI, a nondepolarizing NMB agent would be the most appropriate choice. This was based primarily on the safety profile and, with respect to ICP reduction, less variability across the literature.

Neuromuscular blocking agents should only be used in patients who have received adequate analgesia and sedation. In addition, NMB has potential adverse effects that should be considered. With prolonged use of NMB, there is potential for critical care polyneuropathy and myopathy. In addition, the use of NMB may prolong ventilator and intensive care unit (ICU) duration. However, given that many patients with severe TBI will have prolonged ventilator courses, the association between NMB and prolonged ventilator use has not been adequately studied in severe TBI.

**Targeted Temperature Management**

The maintenance of normothermia or induction of hypothermia is a debated topic in the care of patients with severe TBI. The BTF guidelines do not recommend or dissuade practitioners from using prophylactic hypothermia, but they do mention that level III evidence suggests use of hypothermia is associated with better clinical outcomes. Since 2007, some key articles have been published on this management strategy. The NABIS: H II (National Acute Brain Injury Study: Hypothermia II) trial evaluated the early use of hypothermia in patients with nonpenetrating head injuries. Patients were rapidly cooled
to 33°C and maintained at that temperature for 48 hours. Overall, the trial failed to show that the use of hypothermia was beneficial in this population. A meta-analysis in 2008 evaluated the use of normothermia and hypothermia in patients with neurologic injury. Although the investigators did not find an association with improved outcomes with lowering of body temperature, they consistently found that fever and higher body temperature were associated with worse clinical outcomes (e.g., Glasgow Outcome Scale, Barthel Index, Modified Rankin Scale). A more recent meta-analysis also evaluated the use of hypothermia in patients with neurologic injury but did not find a statistically significant difference in clinical outcome. Because of these results and the recommendations by the BTF, it is conservative to say that hyperthermia is inappropriate in this patient population; however, with respect to improved clinical outcomes, the data surrounding the use of hypothermia versus the maintenance of normothermia are more equivocal.

If practitioners choose to use hypothermia or actively maintain normothermia, consideration should be given to changes in the pharmacokinetic profile of commonly used medications. In the setting of hypothermia, many medications have been shown to have prolonged elimination times, thus increasing the potential for toxicity in these patients.\textsuperscript{41,42}

**Steroids**

**Progesterone**

Animal studies and small human trials evaluating the use of progesterone early after TBI showed promising results. In fact, in the phase II Progesterone for the Treatment of Traumatic Brain Injury trial (ProTECT), patients who received progesterone had significantly less mortality at 30 days compared with placebo (RR 0.43; 95% CI, 0.18–0.99).\textsuperscript{43} In a separate study, patients with diffuse axonal injury who received progesterone had improved clinical outcomes.\textsuperscript{44} These results were very encouraging to practitioners caring for patients with severe TBI.

Unfortunately, when progesterone was evaluated in a large-scale phase III trial, PROTECT III, the results were not as robust as in earlier trials. The trial included a much larger sample of 1,140 patients (100 patients in ProTECT II) and did not show an improvement in favorable outcomes (RR 0.95; 95% CI, 0.85–1.06; p=0.35).\textsuperscript{45} In a second large study, the SYNAPSE (Study of the Neuroprotective Activity of Progesterone in Severe Traumatic Brain Injuries) trial, progesterone did not show a significant difference in mortality or clinical outcome.\textsuperscript{46} The results of these trials were based on the evaluation of the Glasgow Outcome Scale - Extended (GOSE). The GOSE may not be precise enough to find a difference in this patient population. Therefore, the results currently suggest that in patients with severe
TBI, progesterone does not improve clinical outcomes. Reevaluation of this treatment modality may be warranted if more precise outcome tools are developed.

**Corticosteroids**

Corticosteroids should not be used in patients with TBI. The BTF guidelines give level I evidence against the use of corticosteroids for improving outcomes or reducing ICP. These recommendations were based on a wide range of evidence but primarily on the results of the Corticosteroid Randomisation After Significant Head Injury (CRASH) trial. This trial evaluated the use of high-dose methylprednisolone (2-g intravenous load followed by 0.4 g/hour) in patients with TBI having a GCS of less than 14. The trial planned to enroll 20,000 people but was terminated early after the corticosteroid group was shown to have a higher mortality rate.

**Supportive Care**

**Seizure Prophylaxis**

Posttraumatic seizures are relatively common in patients with severe TBI. The BTF guidelines give level II evidence to support the use of anticonvulsants up to 7 days for the prevention of early posttraumatic seizures. However, the use of anticonvulsants is not associated with decreased rates of late seizure activity (i.e., seizures after 7 days post ictus). This is primarily based on the work of N.R. Temkin and others, who evaluated the use of phenytoin and other anticonvulsants for the prevention of seizures after TBI. It is not usually recommended to use valproate because of the potential risk of increased mortality.

The use of anticonvulsants with fewer adverse events compared with phenytoin has been of interest to practitioners. The data suggest that levetiracetam is as effective as phenytoin at preventing seizures, but with fewer adverse events. In one study by Jones et al., patients who received levetiracetam 500 mg intravenously every 12
hours for 7 days were compared with a historical control of patients who received phenytoin for 7 days. Although there was no difference in the number of seizures, patients who received levetiracetam had a higher incidence of abnormal electroencephalography readings.\textsuperscript{59} However, compared with other trials, the dose used by Jones et al. may have been too low. In an evaluation of levetiracetam pharmacokinetics in neurocritical care patients, patients receiving 500 mg intravenously every 12 hours had a low probability of achieving a trough concentration of 6–20 mcg/mL. Doses of up to 1,500–2,000 mg every 12 hours were needed to have the best probability of achieving an appropriate serum concentration of levetiracetam.\textsuperscript{60} Given this and levetiracetam’s pharmacokinetic properties, some practitioners have considered a loading dose of 15–20 mg/kg followed by a maintenance dose of 1000–1500 mg every 12 hours. However, data are sparse to suggest the most appropriate dose of levetiracetam for seizure prophylaxis in patients with TBI. In addition, some data suggest that levetiracetam has neuroprotective activity. A trial by Szaflarski et al. found that, compared with patients treated with phenytoin, patients treated with levetiracetam had a lower 3-month disability rating scale.\textsuperscript{61} Although not particularly robust, the results do suggest that patients treated with levetiracetam had a better clinical outcome but no difference in mortality. Thus, the use of levetiracetam may be considered a viable alternative to phenytoin for the prevention of early seizures after TBI.

\textbf{Venous Thromboembolism Prophylaxis}

Patients who experience a severe TBI should be considered at high risk of developing a venous thromboembolism (VTE). The benefit of using chemical VTE prophylaxis in this patient population must be balanced against the risk of increasing intracranial hemorrhage. The BTF guidelines quote level III evidence to recommend the use of “low-molecular-heparin or low-dose unfractionated heparin in combination with mechanical prophylaxis.” They note that this recommendation comes with the risk of worsened intracranial hemorrhage.\textsuperscript{62} Recent data from a retrospective study suggest that the use of chemical VTE
prophylaxis did not increase intracranial hemorrhage volume. However, because of the low observed rate of increased intracranial hemorrhage, these results may be the product of a type II statistical error.

A small study addressed the question of when VTE prophylaxis should be implemented in these patients. The study evaluated the use of enoxaparin or placebo in 62 patients with unchanged cranial computed tomography (CT) scans at 24 hours after injury. The study found that, with respect to hematoma expansion, there was no difference between the two groups. However, this study included only patients with mild to moderate TBI and those with small radiographic findings. These results may not be applicable to patients with larger radiographic findings or patients with severe TBI. In a retrospective study by the Western Trauma Association, patients who received low-molecular-weight heparin (LMWH) were compared with those who did not receive systemic anticoagulation. These patients had moderate to severe TBI, and patients in the LMWH group appeared to have worse injuries. Although the patients who received LMWH had a higher percentage of hemorrhage progression compared with those who did not receive LMWH, the timing of when the LMWH was initiated did not affect hemorrhage progression rates. Thus, the worse injuries in the LMWH group could have confounded the outcome on hemorrhage progression but should not have influenced the results associated with the timing of administration.

According to the observed data and the BTF guidelines, the use of chemical VTE prophylaxis in addition to mechanical VTE prophylaxis is warranted. In addition, the conservative approach to the addition of LMWH or low-dose unfractionated heparin would be to start within 24–48 hours of the last stable cranial CT scan.

**Tranexamic Acid**

The CRASH-2 trial has shown a potential mortality benefit for using tranexamic acid in bleeding trauma patients. A subanalysis of that trial showed that patients who received tranexamic acid had smaller hematoma expansions than did patients not receiving tranexamic acid.
However, this result did not reach statistical significance. This has led to the development of CRASH-3, which will be a large study evaluating mortality in patients with severe TBI who receive tranexamic acid. Until the results of this trial are released—and given the significant risk of thrombosis associated with tranexamic acid—the use of tranexamic acid in patients with severe TBI is undefined.

**Investigational Therapies**

Most pharmacotherapeutic modalities for severe TBI are aimed at the prevention or modulation of secondary injury. The mechanisms for secondary injury are diverse and largely ill defined. Thus, many potential therapies are being investigated. Many of these such as statin use, growth hormone replacement, prostacyclin supplementation, and brady-kinin B$_2$ receptor antagonists are aimed at reducing the inflammatory process. However, these potential treatment strategies are early in development.

---

**ACUTE SPINAL CORD INJURY**

**Epidemiology and Pathophysiology**

Acute spinal cord injury (SCI) is a physically and emotionally devastating traumatic event warranting ICU care to minimize morbidity and mortality in patients surviving the initial event. Acute mortality ranges from 48% to 79%, and another 4.4%–16% of patients will die before hospital discharge. Perhaps even more tragic is that more than half of the cases are individuals between age 16 and 30, with just less than 80% being males according to the National Spinal Cord Injury Statistical Center. The average age for patients with SCI is 29 years. The prevalence of acute SCI is estimated at 17,000 new cases (54 cases per 1 million) annually in the United States according to 2012 data. This is a modest increase from 1993. This does not include those who die at the scene of the accident. About 31% of SCI cases
are a result of motor vehicle collisions. The next most common etiology is falls (40.4%), followed by firearm injuries (5.4%). The incidence of falls has increased significantly during the past 2 decades, largely in older adult patients. Median hospital length of stay for SCI is 11 days since 2010, resulting in average first-year expenses of $342,111–$1.05 million, depending on injury severity. Less than 1% of patients with SCI have complete neurologic recovery by the time of hospital discharge.

It is recommended that evaluations of acute SCI use the American Spinal Injury Association (ASIA) International Standards for Neurological Classification of Spinal Cord Injury recommendations (level II). The ASIA examination worksheet can be downloaded free of charge at the ASIA website. Motor and sensory assessments are done with these instruments, resulting in the classification of patients according to the injury spine level (e.g., cervical spine 5 [C5], thoracic spine 6 [T6]). Patients are also classified as having complete or incomplete injuries. The latter reflects sensory and/or motor function preserved below the specified level. Three ASIA incomplete injury subcategories are available to further delineate patients for assessment and prognosis (see Box 20.1). Central cord syndrome is yet another classification for patients with acute SCI. This term is used for patients with the atypical presentation of relative preservation of lower extremity function compared with the upper extremities. Patients with tetraplegia have sustained injuries to one of the eight cervical segments of the spinal cord, whereas patients with paraplegia have had cord injuries in the thoracic, lumbar, or sacral regions. Incomplete tetraplegia (40.6%) followed by incomplete paraplegia (18.7%) are the most common neurologic categories among patients with SCI. Complete tetraplegia injuries occur in about 12% of patients with SCI.

Similar to acute TBI, the pathophysiology of acute SCI involves both primary and secondary injuries. Pri-mary injury results from a mechanical insult to the spinal cord from compression, contusion, laceration, flexion, extension, rotation, or shearing forces. Ischemia caused by damage to the adjacent vasculature, systemic hypotension,
and hypoxemia is also integral to the pathophysiology of acute SCI in addition to direct damage to the spinal cord. The concept of secondary injury encompasses many processes ranging from edema and inflammation to apoptosis and necrosis. No therapy to date has been shown to attenuate these processes resulting in improved outcomes after acute SCI. Nevertheless, there are data that treating patients with acute SCI within an ICU setting is beneficial in minimizing morbidity and mortality as well as reducing the economic burden for patients after this catastrophic injury. This occurs through prompt and aggressive hemodynamic and respiratory stabilization and subsequent prevention of associated complications. Unstable spine fractures and/or dislocation must be recognized and surgically managed in a timely manner as well.

The Joint Section on Disorders of the Spine and Peripheral Nerves of the American Association of Neurological Surgeons (AANS) and the Congress of Neurological Surgeons (CNS) has published comprehensive and evidence-based guidelines for the management of acute cervical spine and SCIs. The AANS/CNS guidelines, first published in 2002 and revised in 2013, provide the most authoritative recommendations for the treatment of these patients. The evidence levels from the AANS/CNS guidelines are listed where applicable. A treatment algorithm for SCI can be found in Figure 20.3.

**Acute Cardiopulmonary Management**

**Ventilation**

Concurrent with spine stabilization to prevent further injury, the initial priority in patients with acute SCI is cardio-pulmonary management. Acute SCI can have profound effects on the mechanics of ventilation because of the loss of diaphragmatic function above C5 and loss of accessory muscles with damage in the C4–C8 regions of the spinal cord. Relative hypoxemia and exacerbated spinal cord hypoxemia can also occur because of diaphragmatic function. Thus, patients with acute SCI often require intubation and mechanical ventilation. The
duration of mechanical ventilation typically depends on injury level and complete versus incomplete injury. A tracheostomy is warranted in some patients requiring long-term mechanical ventilation (greater than 2 weeks).\textsuperscript{74} Although mechanical ventilation is lifesaving for many patients with SCI, pneumonia is an inevitable risk because of this supportive care.\textsuperscript{83} As such, prevention of pneumonia through reducing oropharyngeal secretion aspiration and possible alteration of digestive flora should be a priority in patients with SCI to minimize morbidity and mortality.\textsuperscript{84} Not unlike any other critically ill patients with ventilator-associated pneumonia, patients with SCI developing pneumonia should promptly begin broad-spectrum antimicrobial therapy.

**Box 20.1. ASIA Impairment Scale (AIS)**

**A = Complete.** Not sensory or motor function is preserved in the sacral segments S4–5.

**B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4–5 (light touch or pinprick at S4–5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

**C = Motor Incomplete.** Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments (S4–5) by LT, PP, or DAP) and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body.

(This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade $\geq 3$.

**D = Motor Incomplete.** Motor incomplete status as defined
above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade $\geq 3$.

**E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor, and NLI levels; the ASIA Impairment Scale grade; and/or the zone of partial preservation (ZPP) when they are unable to be determined according to the examination results.

---

S = sacral; L = lumbar; LT = light touch; PP = pinprick, DNP = deep anal pressure; NLI = neurologic level of injury.

1 Suspected SCI

2 Immobilize neck and spine
   Ensure adequate oxygenation, establish airway

   Stress ulcer prophylaxis
   Urinary catheterization
   Evaluation of GI motility, nutrition support options
   Monitor vital signs and neurologic status
Blood Pressure Stabilization

Reversal of hypotension (systolic blood pressure less than 90 mm Hg) is recommended as soon as possible (level III) with a goal mean arterial pressure of 85–90 mm Hg for the first 7 days (level II). Augmentation of blood pressure reduces morbidity and mortality and reduces the length of stay. Because of trauma-related hypovolemia from concurrent injuries or neurogenic shock, hypotension may be present. Neurogenic shock is a form of distributive shock that occurs secondary to loss of sympathetic innervation to blood vessels and the heart as well as unopposed parasympathetic tone in patients with injuries above T6. The incidence of neurogenic shock is about 19% in patients with cervical cord injuries and 7% in patients with thoracic injury. This complication manifests as vasodilation, decreased heart rate, and decreased cardiac output. Aggressive fluid resuscitation with crystalloids or red blood cell transfusion if the patient is anemic is often required for restoration of blood pressure together with adrenergic agents such as dopamine and norepinephrine. Although albumin therapy may be considered an alternative to crystalloid fluid resuscitation after acute SCI, a retrospective analysis of 460 patients with TBI showed an increase in mortality (33.2%) compared with patients receiving 0.9% normal saline, indirectly bringing this practice into question. Atropine is often used in patients with neurogenic shock having bradycardia. Phenylephrine should be avoided in patients with hypotension and bradycardia because it is essentially devoid of beta activity. Invasive monitoring is usually needed in patients requiring vasopressor support. Ortho-static hypotension in the subacute period may be seen. Pharmacologic therapy for this complication includes
fludrocortisone, midodrine, and pseudoephedrine.\textsuperscript{74,87}

**Thermoregulation**

Temperature dysregulation with resultant hypothermia and hyperthermia also commonly occurs after SCI.\textsuperscript{80} Furthermore, patients with acute SCI may have sweating disturbances (i.e., hyperhidrosis and anhidrosis).\textsuperscript{80} These can occur secondary to damage to autonomic pathways to the skin. As such, close attention to body temperature in patients after acute SCI is warranted. Hypothermia may require warming techniques, whereas hyperthermia may necessitate cooling of the patient.

**Prevention and Management of Acute Complications**

Prevention of a VTE after acute SCI is another priority for patients with SCI after cardiopulmonary stabilization. The greatest risk of a VTE is 72 hours to 2 weeks post-injury, with an incidence that may exceed 80%.\textsuperscript{74} As such, both the American College of Chest Physicians Antithrombotic Therapy and Prevention of Thrombosis guidelines and the AANS/CNS guidelines recommend early prophylaxis to prevent VTE formation and associated morbidity in patients with acute SCI (level I).\textsuperscript{88,89} Neither sequential compression devices nor low-dose unfractionated heparin alone is deemed adequate.\textsuperscript{88} Alternatively, combination therapy with mechanical devices and prophylactic dosing of an LMWH or unfractionated heparin is recommended (level I).\textsuperscript{88} Consideration of placement of a vena cava filter in patients with therapeutic failure is noted but not recommended as a routine prophylactic measure (level III).\textsuperscript{88} Physical examination monitoring for deep venous thrombosis is especially important in patients with SCI because the symptom of pain that usually accompanies this complication may be absent.

Musculoskeletal, visceral, and neuropathic pain at or below the injury level are common after SCI. This complication can have a major effect on the quality of life and psychological well-being of the patient, often
leading to anxiety and depression. The International SCI Pain Basic Data Set is recommended as the preferred means to assess pain in patients with SCI (level I). This tool, which is available on the NINDS (National Institute of Neurological Disorders and Stroke) website, evaluates pain severity, physical functioning, and emotional functioning. Depression after acute SCI is common and can occur independently of the pain often associated secondarily with other psychiatric illnesses. Psychotherapy and/or pharmacologic treatment may be needed for both pain and psychological management, acutely and chronically. However, no specific recommendations are available for patients with acute SCI having these conditions. As such, therapy should be individualized to the greatest extent possible, including if and when pharmacologic therapy should be initiated. Relative to neuropathic pain, anticonvulsants are commonly used in the management of this condition in patients with acute SCI, not unlike other patient populations.

Nutrition support should begin as soon as feasible (less than 72 hours) after SCI (level III). The rationale for this supportive care in patients with SCI is the hypermetabolism, inherent immobility, and muscle atrophy typically present after injury. Although nutrition support is safe, no effect on neurologic outcome has been shown (e.g., decreased infection, ventilator hours, length of stay). Noteworthy is that impaired peristalsis, a gastrointestinal (GI) complication of acute SCI, may initially compromise the use of enteral feedings in patients with SCI. Close monitoring of bowel sounds, gastric residual volumes, and bowel movements is needed to facilitate nutrition support of patients with SCI having no complications (e.g., aspiration). Use of stool softeners and laxatives is also commonly needed as adjunctive therapy to facilitate stool evacuation in patients with SCI. Prophylaxis therapy for stress-related mucosal disease (e.g., histamine-2 receptor antagonists, proton pump inhibitors) should usually be administered acutely in patients with SCI, especially those requiring intubation and/or with evidence of relative hypotension. After the risk of stress-related mucosal disease diminishes (e.g., cardiopulmonary stabilization, extubation), discontinuation of these agents is advocated.
Pneumonia is not the only acute infectious complication experienced after SCI. Urinary tract infections are also very common in patients with SCI because of impaired bladder emptying associated with a neurogenic bladder and the inherent need for urinary catheters continuously or intermittently. Evaluating patients with SCI for evidence of a urinary tract infection, including urinary cultures, is warranted in any patient with fever, leukocytosis, and other generalized systemic signs of infection. Patients with acute and chronic SCI should also receive meticulous skin care because they are at risk of developing pressure ulcers that can become secondarily infected. Log-rolling patients and using rotokinetic beds are strategies for avoiding this challenging complication.

Neuroprotective Therapy

Corticosteroids

Interest in using glucocorticoids as a pharmacologic strategy for improving neurologic outcomes in SCI has existed for decades.\textsuperscript{74,95} Postulated mechanisms for the beneficial effects of corticosteroids in SCI include increasing cell membrane integrity, decreasing inflammation and free radical production, and limiting vasogenic edema through stabilization of the blood–spinal cord barrier. Three major clinical trials investigating the efficacy of methylprednisolone have been conducted since the 1980s. These trials are usually called the National Acute Spinal Cord Injury Study (NASCIS) I–III. The first of these studies (NASCIS I) compared motor and sensory scores in individuals with SCI after administration of either a 100- or 1000-mg bolus dose of methylprednisolone followed by a daily dose for 10 days without a placebo control.\textsuperscript{96} No differences in outcomes were seen between the two groups. In NASCIS II, the dose of methylprednisolone was increased, and individuals with SCI were randomized to three different treatments: (1) methylprednisolone (30-mg/kg bolus followed by 5.4 mg/kg/hour for 23 hours), (2) the opioid antagonist naloxone (5.4-mg/kg bolus followed by 4.0 mg/kg/hour for 23 hours), and (3)
In a post hoc analysis, the investigators reported improved motor and sensory scores at 6 months if methylprednisolone was administered within 8 hours of injury. This finding was immediately embraced as the standard of care for acute SCI. A third trial (NASCIS III) randomized patients to receive methylprednisolone for 24 or 48 hours or the antioxidant tirilazad mesylate for 48 hours after a bolus of methylprednisolone. Neurologic outcomes were similar for all treatment groups if initiated within 3 hours of injury. When comparing individuals treated between 3 and 8 hours after injury, motor scores and functional measures were improved at 6 weeks and 6 months in participants treated with methylprednisolone for 48 hours. The findings from this study became the new standard of care for 15 years thereafter.

Despite having many advocates, the NASCIS trials were always deemed questionable by many clinicians and scientists. One major reservation was the association of methylprednisolone administration with an increased incidence of pulmonary embolism, pneumonia, wound infection, sepsis, and GI complications in NASCIS II and III. Other methodological flaws have also been identified, including a post hoc versus prospectively defined administration time window (i.e., 8 hours), inclusion of patients with minimal deficits and lesions below T12, lack of functional measures, and no standardization with respect to surgical or medical treatment. On review of these data, the AANS/CNS guidelines recommend against using methylprednisolone in the management of SCI (level I), reversing the standard of care for more than 2 decades.

Gangliosides

In addition to corticosteroids, an agent known as GM1 ganglioside was one of the most widely studied pharmacologic agents in acute SCI in the past. This was based on animal studies showing increased neural plasticity, decreased excitotoxicity, and apoptosis in SCI models. Unfortunately, a large prospective, multicenter, randomized trial of low-dose GM1 ganglioside, high-dose GM1 ganglioside, and placebo in 797 patients with acute SCI was unable to show any difference in neurologic outcome between the treatment groups. Noteworthy and
potentially confounding the study results, all patients enrolled in this trial received methylprednisolone as described in the NASCIS II study.

Other Therapies

In light of no single pharmacologic agent being available to heal the injured spinal cord and restore function, other investigational strategies have been evaluated. These other approaches have usually paralleled clinical studies of patients with TBI. One example is progesterone that has been investigated as a neuroprotective agent in animal models of acute SCI. Interest in local or systemic therapeutic hypothermia has existed for years, based on preclinical studies. The rationale of therapeutic hypothermia is to attenuate the secondary inflammatory processes after acute SCI. However, there are a paucity of controlled comparative clinical data relative to the beneficial effects of this treatment strategy after acute SCI. As such, the AANS/CNS issued a level IV recommendation stating that evidence is insufficient for or against this practice. One unique therapy is antihuman Nogo-A antibody administered intrathecally. Nogo-A is an inhibitory molecule that limits regenerative sprouting of injured axons. A prospective, multicenter trial of this agent is currently under way in patients with complete and incomplete SCI. In addition, other targeted anti-inflammatory agents offer promise in modulating the inflammatory response after acute SCI. Finally, using mesenchymal stem cell transplantation as a regeneration strategy for restoring the injured spinal cord is being investigated. However, many challenges await clinical application of this treatment approach.

LEARNING OBJECTIVES

1. Recognize the risk factors, signs, and symptoms of acute ischemic stroke (AIS).
2. Determine eligibility for thrombolytic medications using patient-specific factors.
3. Manage and monitor blood pressure in patients with AIS.
4. Define the role of endovascular treatment for AIS including the role of intra-arterial tissue plasminogen activator.
5. Prevent hospital complications by providing supportive care to patients with AIS.
6. Discuss the etiology, risk factors, and clinical presentation of hemorrhagic stroke.
8. Provide recommendations for reversal of anticoagulation in patients receiving warfarin and the non-vitamin K antagonist oral anticoagulants.
10. Understand the role of dedicated stroke units in the care of patients with stroke.
INTRODUCTION: ACUTE ISCHEMIC STROKE

Ischemic stroke, or brain attack, is a debilitating condition that often leads to disability, family hardship, increase in direct and indirect health care costs, and death. Transient ischemic attack (TIA), termed mini-stroke, precedes stroke in 60% of patients and should be viewed as a warning sign for impending stroke. Symptoms of TIA are similar to those of stroke but resolve in less than 24 hours. However, this definition is problematic because up to one-third of patients with symptoms for less than 24 hours have evidence of infarction. This has led to a new “tissue-based” definition for TIA as a transient episode of stroke symptoms without radiologic evidence of infarction.
EPIDEMIOLOGY

Each year, around 800,000 people in the United States have a stroke, with about 90% of those related to ischemia. Ischemic strokes are further classified as atherosclerotic, cardioembolic (e.g., atrial fibrillation, valvular disease), lacunar, atypical (e.g., dissection, drug abuse), and cryptogenic in up to one-third of cases. Prevalence of ischemic stroke is highest in African Americans and American Indians or Alaskan natives. Strokes are more common in the southeastern United States than in other areas. These are the so-called “stroke belt” states.

PATHOPHYSIOLOGY

Whether because of atherosclerosis or embolism, the initiating event in patients with acute ischemic stroke (AIS) is cerebral arterial occlusion. Depending on the severity and duration of the occlusion, ischemic brain injury may occur as a result of several pathobiologic processes. The ischemic penumbra is an area thought to surround the core ischemic area and may represent salvageable neurons. Blood flow to this area is below normal but may be augmented by the presence of collateral flow from surrounding blood vessels. Under normal conditions, cerebral blood vessels dilate in an attempt to maintain consistent blood flow, which is termed autoregulation (Figure 21.1). For instance, normotensive patients “autoregulate” within a mean arterial pressure (MAP) zone of about 50–150 mm Hg, whereas hypertensive patients have a shift of the autoregulation curve to the right and autoregulate at higher MAP ranges. However, auto-regulation is impaired in the penumbra (area of ischemic but viable brain tissue), and a decrease in blood pressure can lead to a decrease in cerebral blood flow. Pharmacologic interventions may be most effective in preventing ischemic injury within the penumbra. Without emergency restoration of perfusion to the penumbra, propagation of neuronal cell death occurs.

CLINICAL PRESENTATION
Symptoms of AIS commonly include sudden onset of numbness or weakness in the face or extremities, especially on one side of the body. Visual and speech impairment are also common, as are dizziness, loss of balance, and headache. Depending on the location of the stroke, very distinct patterns of impairment may manifest. Strokes occurring in the upper lobes of the brain (cerebrum) may cause hemiparesis (weakness) or hemiplegia (paralysis) on the contralateral side. In addition, other common deficits include visual, memory, speech, and cognition. Cerebellar strokes may cause headache, nausea, vomiting, and problems with coordination and balance (ataxia). Finally, brain stem strokes may lead to loss of respiratory stimulation, heart function, temperature regulation, and ability to chew or swallow.

**DISEASE CLASSIFICATION, RISK FACTORS, AND DIAGNOSIS**

Eighty-seven percent of all strokes are ischemic and can further be classified as atherosclerotic, penetrating artery disease, cardiogenic (e.g., atrial fibrillation, myocardial infarction), and cryptogenic. Non-modifiable risk factors for AIS include age older than 55 years, male sex, family history, prior stroke or TIA, and African American race. Modifiable risk factors include hypertension (most important), atrial fibrillation, diabetes mellitus, hyperlipidemia, drug use (smoking, alcohol abuse, cocaine), physical inactivity/obesity, carotid stenosis, and oral contraceptive use. Although increasing age is an important risk factor for stroke, the average age of stroke onset has been declining, and in 2009, about one-third of patients hospitalized with stroke were younger than 65 years. In addition to an increase in prevalence of traditional risk factors, stroke in younger adults has been associated with migraines, drug use (e.g., cocaine and cannabis), patent foramen ovale, pregnancy, and oral contraceptive use.

Emergency medical service personnel can identify patients with stroke before arrival to the hospital using assessment tools such as the Cincinnati Prehospital Stroke Scale or the Los Angeles Prehospital Stroke Screen (Table 21.1).
TREATMENT

On arrival to the hospital, the American Heart Association has published detailed guidelines regarding the management of stroke in the emergency department (ED). These guidelines include several interventions that should be performed in a timely manner according to recommendations from the National Institute of Neurological Disorders and Stroke (NINDS) (Figure 21.2). One of the most important steps is performing a detailed patient history and clearly identifying the time of symptom onset. Neurologic assessment should be done within 25 minutes of ED arrival, usually incorporating the National Institutes of Health Stroke Scale (NIHSS). Computed tomography (CT) scanning of the head should be done and evaluated within 45 minutes of ED arrival to exclude hemorrhagic stroke. Intravenous tissue plasminogen activator (TPA) should be administered to eligible patients within 60 minutes of arrival to the hospital. Of note, these time goals are “worst-case scenario” because AIS is a medical emergency requiring interventions as soon as possible (“time is brain tissue”). Clinical scenarios that may mimic stroke signs need to be ruled out before a diagnosis of stroke and include hypoglycemia, encephalopathies, postictal state, mass lesions (e.g., brain tumor, brain abscess, head injury), conversion disorder, drug toxicities, and complicated migraine.
Criteria for Intravenous TPA Administration

Intravenous TPA is the only medication shown to improve outcome in AIS and should be administered as soon as possible to all eligible patients. Criteria for administration of intravenous TPA within 3 hours of symptom onset are directed by the NINDS protocol, whereas additional exclusion criteria for administration 3–4.5 hours from symptom onset are guided by the European Cooperative Acute Stroke Study (ECASS) III protocol (Box 21.1).\textsuperscript{7,8}

Although several laboratory and diagnostic studies are recommended in the evaluation of a patient with AIS, the only laboratory result required before intravenous TPA administration is blood glucose concentration (because this is a stroke mimic). However,
if a bleeding abnormality is expected or the patient has a known or uncertain anticoagulation status, it is reasonable to await the results of coagulation studies before intravenous TPA administration. In patients receiving direct oral anticoagulants (e.g., factor Xa inhibitors or direct thrombin inhibitors) with an unclear history regarding the last dose taken, laboratory assessment may be helpful to assess the risk-benefit of intravenous TPA administration. For direct thrombin inhibitors, a normal TT (thrombin time) and aPTT (activated partial thromboplastin time) suggest that the concentration of dabigatran is very low. Anti-factor Xa assays are preferred to confirm the concentration of factor Xa inhibitors but may not be available at many institutions. In this instance, prothrombin time (PT) may be used instead, but PT may be normal with “on-therapy” rivaroxaban concentrations because the effect on PT is highly dependent on the reagent used in the PT test.⁹

Figure 21.2  Algorithm for the management of acute ischemic stroke.

IA = intra-arterial; IV = intravenous; TPA = tissue plasminogen inhibitor.

Monitoring and Adverse Effects of Intravenous TPA
Bleeding is the most worrisome adverse effect associated with intravenous TPA administration, with intracerebral hemorrhage (ICH) the most serious (termed hemorrhagic conversion). The rate of symptomatic ICH was 6.4% in the NINDS trial and 7.9% in ECASS III when using the same definition as in NINDS.8,10 Because of the importance of strict adherence to administration criteria for intravenous TPA, a 15.7% rate of symptomatic ICH was reported in a cohort of patients who often received the drug outside the therapeutic window or had protocol violations.11 Other factors that increase the risk of ICH after intravenous TPA administration include increasing age and stroke severity, hyperglycemia, presence of edema/mass effect on the initial head CT, and hypertension. Recommendations and treatment options for blood pressure monitoring are summarized in Table 21.2.

Neurological monitoring should be performed often during and for the initial 24 hours after intravenous TPA administration. Patients who develop severe headache, acute hypertension, nausea, vomiting, or seizure or who have a worsening neurological examination should have intravenous TPA discontinued and an emergency head CT performed.

Angioedema is another potentially serious adverse effect of intravenous TPA, occurring in 1.3%–5.1% of patients. The proposed mechanism is an increase in the vasodilator bradykinin caused by cleavage with TPA-generated plasmin of high-molecular-weight kininogen.12 Risk factors include African American race, use of angiotensin-converting enzyme inhibitor medications, and strokes involving the insular and frontal cortex. Monitoring should include visual inspection of the tongue, lips, and oropharynx. Symptoms may be asymmetric and appear on the side contralateral to the ischemic infarct.13 Mechanical ventilation may be necessary if edema involves the larynx, hypopharynx, oropharynx, or palate as opposed to edema isolated to the lips or anterior tongue. Medical treatments described in case reports have been variable, but a short course of corticosteroids and antihistamines is probably warranted in patients requiring mechanical ventilation.12
Box 21.1. Criteria for Administration of Intravenous TPA

Within 3 hours of symptom onset

Inclusion criteria

1. Age $\geq 18$ years
2. Clinical diagnosis of AIS with a measurable neurologic deficit
3. Clearly established time of symptom onset $< 3$ hours

Exclusion criteria

1. Evidence of intracranial hemorrhage on CT scan
2. Multilobar infarction (hypodensity $> 1/3$ cerebral hemisphere)
3. History of intracranial hemorrhage
4. Blood pressure remaining $> 185/110$ mm Hg at time of intravenous TPA administration despite treatment
5. Arteriovenous malformation, neoplasm, or aneurysm
6. Witnessed seizure at stroke onset
7. Active internal bleeding or acute trauma (fracture)
8. Platelet count $< 100,000/mm^3$
9. Heparin administration within 48 hours resulting in aPTT $> \text{upper limit of normal}$
10. Anticoagulant use with INR $> 1.7$ or PT $> 15$ seconds
11. Intracranial or intraspinal surgery, serious head trauma, or previous stroke within 3 months
12. Arterial puncture at noncompressible site within 7 days

Relative contraindications

1. Minor or rapidly improving stroke symptoms
2. Major surgery/trauma within 14 days
3. GI or urinary tract hemorrhage within 21 days
4. Myocardial infarction within 3 months
5. Post-myocardial infarction pericarditis
6. Blood glucose concentration < 50 or > 400 mg/dL
7. Additional criteria 3–4.5 hours from symptom onset

Exclusion criteria
1. Age > 80 years
2. Severe stroke defined as NIHSS > 25
3. Taking oral anticoagulant regardless of INR
4. History of both diabetes and previous AIS

AIS = acute ischemic stroke; TPA = tissue plasminogen activator.

Other Fibrinolytic Agents

Although intravenous TPA is the only U.S. Food and Drug Administration (FDA)-approved fibrinolytic for AIS in the United States, tenecteplase, bioengineered from 3 amino acid substitutions on human tissue plasminogen activator (alteplase), has increased fibrin specificity, has a longer half-life (22 minutes vs. 3.5 minutes), and is less susceptible to PAI-1 (plasminogen activator inhibitor-1) compared to alteplase.\textsuperscript{14} In a randomized controlled phase IIb trial of patients with AIS presenting within 6 hours of symptoms, patients who received tenecteplase had significantly improved reperfusion, NIHSS scores, and excellent or good recovery at 90 days compared with alteplase, with a nonsignificant decrease in intracerebral bleeding.\textsuperscript{15} Tenecteplase also has a practical advantage over alteplase because it may be administered as a rapid intravenous bolus compared with a 1-hour
infusion for alteplase. A large Norwegian phase III randomized trial is ongoing (NOR-TEST) to compare 3-month clinical outcomes in alteplase- versus tenecteplase-treated patients presenting within 4.5 hours of AIS symptom onset.\textsuperscript{16} Derived from bat saliva, desmoteplase has a very high fibrin selectivity compared with intravenous TPA, but a recent study (DIAS-3) reported no improvement in functional outcome in patients who received desmoteplase compared with placebo when administered between 3 and 9 hours of symptom onset in AIS.\textsuperscript{17} As such, this drug is no longer in development for the indication of AIS.

**Endovascular Interventions**

Treatment of AIS has evolved beyond intravenous administration of TPA to include endovascular interventions such as intraarterial TPA, mechanical clot aspiration (e.g., Penumbra device) or retrieval (e.g., Merci catheter, Trevo retriever, Solitaire stent retriever), and angioplasty and stenting. These interventions are often used in combination, and in addition to intravenous TPA. For instance, patients eligible for intravenous TPA may receive this intervention followed by endovascular treatment with intra-arterial TPA and clot retrieval. Although intravenous TPA is considered the “gold standard” for AIS, it may be less effective for certain types of strokes such as large middle cerebral artery (MCA) occlusions. Of note, the same “time is brain” principle also applies to any endovascular intervention.

**Table 21.2** Management of Hypertension in Patients with Acute Ischemic Stroke
Intra-arterial TPA

Patients with AIS may have a contraindication to intravenous TPA therapy, commonly presentation outside the time window for intravenous TPA window. Although intra-arterial TPA is not FDA approved for this indication, two clinical trials that used other fibrinolytic agents provide most of the (extrapolated) evidence for intra-arterial TPA. In the Prolyse in Acute Cerebral Thromboembolism II (PROACT II) study, patients who received recombinant pro-urokinase within 6 hours of symptom onset for MCA occlusions had improved modified Rankin scores at 90 days and better recanalization than control. Symptomatic ICH was numerically higher in the treatment group (10%) than in control (2%), but this was not statistically significant. In the MELT (middle cerebral artery embolism local fibrinolytic intervention trial) study, patients who received urokinase within 6 hours of AIS were more likely to have modified Rankin scores of 0–1 (no significant disability) than was control. Symptomatic ICH occurred in 9% of
patients, similar to that seen in PROACT II. Current guidelines recommend intra-arterial fibrinolysis within 6 hours of symptom onset in patients with large MCA strokes who are ineligible for intravenous TPA (class I recommendation) and those with other types of stroke who have a contraindication to intravenous TPA (class IIa recommendation).  

Combination Intravenous Fibrinolysis and Endovascular Interventions

Patients with proximal cerebral artery occlusions (e.g., MCA) often have large clot burdens, greater neurologic deficits, and subsequently increased likelihood of intravenous TPA failure. In this setting, eligible patients receive intravenous TPA and then endovascular administration of intra-arterial TPA if necessary ("salvage" or "rescue" therapy). In the Interventional Management of Stroke (IMS)-1 and IMS-2 trials, patients presenting within 3 hours of symptom onset received a reduced dose of intravenous TPA 0.6 mg/kg (max of 60 mg), followed by intra-arterial TPA up to 22 mg administered by a standard microcatheter or the EKOS microinfusion catheter. Good clinical outcome was reported in both studies (modified Rankin score 0–2) as well as better outcomes than the placebo group from NINDS. Rescue intra-arterial fibrinolysis is currently considered a reasonable approach in patients with large artery occlusion.  

As discussed previously, endovascular interventions are often used in combination. A recent multicenter randomized open-label Dutch study (MR CLEAN) compared endovascular therapy (intra-arterial fibrinolysis, mechanical treatment, or both) plus usual care (mostly intravenous TPA) with usual care alone. Patients were required to receive intra-arterial treatment within 6 hours of symptom onset and have an occlusion of the distal intracranial carotid artery, MCA, or anterior cerebral artery. Intra-arterial fibrinolysis consisted of either alteplase or urokinase with maximum doses of 30 mg and 400,000 international units if intravenous TPA was given (87% of the intervention group). Most patients in the intervention group received mechanical intra-arterial therapy, although the proportion of patients who received intra-
arterial fibrinolysis is unclear. At 90 days, 32.6% of patients were functionally independent (as defined by a modified Rankin score of 0–2) compared with only 19.1% in the usual care group. Symptomatic ICH was reported in 7.7% of patients in the intervention group compared with 6.4% of patients in the usual care group, which was not statistically significant and was similar to bleeding rates from studies of patients who received intravenous TPA only. Of note, 82% of patients in the intervention group from this study received treatment with “modern” retrievable stents, which are more effective than first-generation devices. Success of combination therapy has been confirmed in the ESCAPE (Endovascular treatment for Small Core and Anterior circulation Proximal occlusion with Emphasis on minimizing CT to recanalization times) and EXTEND-IA (Extending the Time for Thrombolysis in Emergency Neurological Deficits–Intra-arterial) studies because endovascular treatment (with primarily the Solitaire stent retrieval device) was superior to intravenous TPA alone.23,24

**Early Antiplatelet Administration**

The CAST (Chinese Acute Stroke Trial) and IST (International Stroke Trial) trials both reported a small benefit from aspirin 160–300 mg/day administered early during hospitalization for AIS.25,26 Current recommendations are to administer aspirin 325 mg/day orally beginning within 48 hours of stroke onset.7 In patients who receive fibrinolysis, an antithrombotic should not be initiated until 24 hours afterward, but may be initiated on hospital day 1 in patients who do not receive fibrinolysis. Patients who fail swallowing studies and have no enteral access may receive aspirin rectally. In patients with aspirin allergy, there is little evidence regarding alternative antiplatelet medications, but it is reasonable to administer clopidogrel with the understanding that a loading dose is necessary to rapidly achieve inhibition of platelet aggregation. Administration of antithrombotic medications by the end of hospital day 2 is a performance measure of the Joint Commission Stroke National Hospital Inpatient Quality Measures for certified stroke centers.
SUPPORTIVE CARE

Temperature Control
Fever is common in patients with AIS and has been associated with poor neurological outcomes. However, hypothermia may be neuroprotective by decreasing metabolic demand, acidosis, calcium influx, free radical production, and production of inflammatory cytokines and excitatory amino acids. Current recommendations are to lower body temperature in patients with a temperature greater than 38°C using antipyretic medications. Surface cooling devices (e.g., Arctic Sun) may also be used in patients with fever who do not respond appropriately to medications. Induced hypothermia for the purpose of neuroprotection is not recommended because of a lack of robust clinical evidence.

Glucose Control
Hyperglycemia on admission and while in hospital has been associated with poor outcomes in AIS and may increase the risk of hemorrhagic conversion. Hypoglycemia may mimic stroke but, when prolonged, can also lead to ischemia and should be urgently treated in patients with AIS. The target blood glucose concentration is unclear, but current recommendations suggest a goal of 140–180 mg/dL.

Intravenous Fluids
Most patients with AIS are either euvoletic or hypovolemic, the latter often requiring administration of intravenous fluids in the acute setting because of impaired swallowing or altered mental status. Hypovolemia may decrease cerebral perfusion and worsen ischemic injury, whereas hypervolemia may exacerbate ischemic brain edema and increase stress on the heart; therefore, euvoletic is recommended in patients with AIS. Intravenous solutions containing substantial amounts of free water (e.g., dextrose 5%, 0.45% sodium chloride) should be avoided.
because of the potential to increase brain swelling.⁷

**Prophylaxis**

**Venous Thromboembolism**

Deep venous thrombosis and pulmonary embolism are potential complications in patients with AIS, likely because of the combination of immobility and the presence of other risk factors for venous thromboembolism (VTE). Mechanical prophylaxis should be used in all patients with immobility and combined with pharmacologic prophylaxis, with the caveat that all anticoagulant medications should be held for 24 hours after fibrinolytic administration. One clinical trial found enoxaparin 40 mg daily to be superior to unfractionated heparin 5,000 units twice daily for the prevention of VTE in patients with AIS, but this trial has been criticized because of the small dose of heparin used.⁷ In the absence of conclusive studies, either low-molecular-weight heparin or unfractionated heparin (5,000 units three times daily for most patients) is a reasonable option for VTE prophylaxis in patients with AIS.

**Seizure**

Seizures after AIS are less common than in patients with ICH, but the incidence may be increased in patients who have hemorrhagic transformation. It is currently not recommended to administer medications for seizure prophylaxis in patients with AIS.⁷ Clinical seizures should be treated, and the risk of non-convulsive seizures should be appreciated in patients with neurological injuries.

**INTRODUCTION: HEMORRHAGIC STROKE**

Stroke consistently ranks as the second leading cause of death around the world, claiming 6.7 million lives in 2012.²⁸ Although hemorrhagic stroke accounts for 10%–20% of strokes, it appears to carry with it a higher mortality rate. One study in Denmark showed a 49.2% mortality
in the hemorrhagic sub-category, whereas ischemic stroke had a mortality of 25.9%\textsuperscript{29}. The National Stroke Association estimates that although hemorrhagic strokes account for only about 15% of strokes, more than 30% of stroke deaths can be attributed to hemorrhages\textsuperscript{30}. A hemorrhagic stroke is defined by a cerebral blood vessel leaking blood into the brain and can be divided further into two categories: ICH and aneurysmal subarachnoid hemorrhage (aSAH). Intracerebral hemorrhage describes a vessel rupture in the brain parenchyma resulting in the formation of a hematoma\textsuperscript{31}. In contrast, aSAH represents the subcategory of stroke that occurs when blood enters the subarachnoid space\textsuperscript{32}. The focus of this chapter will be ICH.

**Epidemiology, Incidence, and Risk**

The incidence of ICH is about 24.6 per 100,000 person-years, making it the most common subtype of hemorrhagic stroke\textsuperscript{31}. The yearly incidence in the United States is about 795,000 people per year, with most being new strokes\textsuperscript{33}. Intracranial hemorrhage appears to be less common in women and has a strong association with age. Those 85 years and older appear to have an almost 10-fold higher yearly risk compared with those 45–54 years. Modifiable risk factors include hypertension (most important), smoking, alcohol use, diabetes mellitus, and anticoagulant/anti-platelet use. Of interest, lower cholesterol and triglyceride concentrations are associated with a higher risk. Other, non-modifiable risk factors include genetic predisposition, cerebral amyloid angiopathy, and Asian ethnicity\textsuperscript{31}. The incidence of ICH secondary to hypertension has decreased over time because of better treatment, yet the overall incidence of ICH has remained steady throughout the years. This has been explained by the increasing incidence of ICH caused by anticoagulant use\textsuperscript{34}.

**Pathophysiology**

Although the pathophysiology of hemorrhagic stroke is not quite as well defined as that of ischemic stroke, it is known that the damage is both
mechanical and chemical. The mechanical damage is secondary to mass effect. A hemorrhage with a volume greater than 30 mL is associated with a significant increase in morbidity and mortality. Mass effect can lead to increased intracranial pressure (ICP), herniation, and death,\textsuperscript{32,33} although the chemical changes occur secondary to the blood components and products of degradation.

Intracerebral hemorrhage occurs after a rupture of a cerebral artery leading to blood entering the parenchymal space. This can be secondary to a complication from a preexisting lesion (e.g., vascular malformation or tumor) and is called secondary ICH. A primary ICH is the result of a hemorrhage in the absence of a clear underlying lesion. Primary is the most common ICH subcategory.\textsuperscript{31} As the hematoma starts to expand, there is an increase in ICP, causing a disruption in local tissue integrity and the blood-brain barrier. The hematoma also leads to an obstruction in venous outflow, thereby causing the release of tissue thromboplastin, leading to local coagulopathy. Cerebral edema then begins to form around the hematoma and can continue to develop over days after the initial insult. In up to 40% of cases, the hemorrhage extends into the cerebral ventricles, leading to another condition known as intraventricular hemorrhage, which is associated with a significantly worse prognosis. The onset of edema can cause mass effect in addition to the hematoma formation, leading to compression of local tissue and neurological dysfunction.\textsuperscript{33}

**Clinical Presentation, Diagnosis, and Severity**

The patient with classic ICH presents with focal neurological deficits progressing over minutes to hours, rather than the typically more abrupt progression seen in AIS. The patient with ICH often has accompanying headache, nausea, vomiting, increased blood pressure, and decreased level of consciousness. The symptoms are typically because of an increase in ICP and evidenced from the Cushing triad (hypertension, bradycardia, irregular respiration). Often, dysautonomia accounting for hyperventilation, tachypnea, bradycardia, fever, hypertension (systolic blood pressure greater than 220 mm Hg), and
hyperglycemia is also present.\textsuperscript{33} Because the symptoms are relatively indistinct, neuroimaging is imperative to diagnosis. Computed tomography is considered the gold standard for identification and is very sensitive for acute hemorrhage identification. Although magnetic resonance imaging (MRI) can be as sensitive for acute identification, it is more sensitive for prior hemorrhage than is CT. However, time, cost, and patient tolerance are some of the considerations that can inhibit emergency MRI. Intracerebral hemorrhage is a medical emergency, and rapid deterioration is not uncommon within the hours after onset. It has been shown that more than 15% of patients have a GCS (Glasgow Coma Scale) score decrease of 2 points or more within the first hour of hospital presentation.\textsuperscript{35,36}

Although there is no widely used standard of grading for the severity of ICH, the most widely validated scoring tool is the ICH score (Table 21.3). It represents a 6-point scale that stratifies the severity according to the five risk factors that were deemed independent 30-day mortality indicators. Table 21.4 represents the 30-day mortality associated with the scoring in the original trial.\textsuperscript{37} Of note, no scoring system for ICH should be used as a solitary prognostic indicator.

**Treatment**

**Anticoagulant Reversal**

As mentioned before, although the incidence of stroke secondary to hypertension is decreasing because of better medical management, those presenting with hemorrhagic stroke secondary to oral anticoagulant use are now estimated to represent 12%–14% of patients with ICH. Therefore, identifying an underlying coagulopathy as a cause and risk of expansion should be at the forefront of the clinician’s mind.

**Vitamin K Antagonists**

If the ICH is related to a vitamin K antagonist (VKA), vitamin K 5-10 mg
intravenously should still be given for international normalized ratio (INR) reversal; however, the onset of even intravenous vitamin K typically begins at around 2 hours and therefore should not be used as the sole reversal agent, but should be part of the reversal algorithm for all VKA-related bleeds. Fresh frozen plasma (FFP), dosed at 10–15 mL/kg, was historically the adjunctive agent used with vitamin K in reversal of VKA, but its use is limited secondary to processing and thawing time, volume to be delivered, and immunologic reactions. The goal of INR reversal varies within the literature but ranges from less than 1.3 to less than 1.5. In more recent years, especially with the addition of the non-vitamin K antagonist oral anticoagulants (NOACs), direct thrombin inhibitors and factor Xa inhibitors to the market, factor products have gained much attention in the treatment of these bleeds. Prothrombin complex concentrates (PCCs) are plasma-derived concentrates that were developed to treat hemophilia. Three-factor PCCs contain factors II, IX, and X, whereas four-factor PCCs also contain factor VII. These products can rapidly be prepared for administration, do not require prolonged administration times, and do not have to be cross-matched, making them operationally advantageous to FFP. A study published in 2013 compared four-factor PCCs with FFP for emergency warfarin reversal with acute bleed (24 were patients with ICH) and found that the rate of achieving an INR less than 1.3 within 30 minutes was 62.2% and 9.6% for four-factor PCC and FFP, respectively. The study also showed similar between-group thromboembolic event rates (7.8% PCC and 6.4% FFP) but described fluid overload more commonly in the FFP group (12.8% vs. 4.9%). However, the literature comparing three- and four-factor PCC is not abundant. A study published in 2015 comparing the effectiveness of three- and four-factor PCC showed that patients who received four-factor PCC and patients who had an INR reversal to 1.5 or less regardless of product were more likely to survive. In the United States, four-factor PCC is labeled for use in emergency reversal of warfarin, and dosing can be found in Table 21.5. However, of note, the four-factor product used in the United States does contain heparin and would be contraindicated in a patient with a history of heparin-
induced thrombocytopenia; therefore, a three-factor PCC product (Profilnine) could be considered as an alternative because the three-factor product Bebulin also contains heparin. Recombinant activated factor VII (rFVIIa) would not be expected to restore the thrombin generation inhibited by a VKA as well as PCC because it does not contain all the inhibited factors and is therefore not recommended for routine use in warfarin reversal. In addition, rFVIIa has been shown to have an increased risk of thromboembolic event, and adding rFVIIa to a three-factor PCC product would not be recommended. A higher risk of thromboembolic events would also be expected when using activated PCCs (factor eight inhibitor bypassing activity [FEIBA]) because of their activated prothrombotic components.

Non-vitamin K Antagonist/NOACs

Although the literature describing the reversal of VKA provides needed guidance, the data describing the reversal of the NOACs is much less dense. Although PCC has been evaluated for use, the data are inconsistent. Increasing the levels of circulating factors is the rationale for using PCCs for VKA; however, in NOACs, the purpose of these products and of factor replacement, in general, is more an attempt to overcome the inhibition by creating a supranormal factor level.45 One study that evaluated the use of four-factor PCC (50 units of factor IX per kilogram) did show a correction of the prolonged PT and abnormal
endogenous thrombin potential in healthy subjects taking rivaroxaban.\textsuperscript{46} However, the data regarding reversal of direct thrombin inhibitors (e.g., dabigatran) are not as convincing.\textsuperscript{47} Activated PCCs (FEIBA) have also been studied for use in NOAC reversal and showed the ability to normalize abnormal thrombin generation times as well as reducing clot initiation time in patients receiving dabigatran. Therefore, it has been suggested that PCC has more of a role in reversal of factor Xa inhibitors, whereas patients with bleeds secondary to direct thrombin inhibitors may benefit from FEIBA (80 international units/kg).\textsuperscript{47} These suggested antidotes for NOACs do not actually affect the ongoing inhibition of the drugs on factors IIa and Xa, and although they may limit the extent of bleeding, the actual outcome in relation to morbidity or mortality is likely minimal.\textsuperscript{48} It is also prudent to note that if doses were recently ingested, charcoal may be an option, and dabigatran is not highly protein bound; therefore, circulating levels can be successfully removed by dialysis. In general, PCC and FEIBA are both reasonable options for the reversal of NOACs in the setting of life-threatening ICH. The results are preliminary, but FEIBA may be a better option in the setting of bleeding secondary to a direct thrombin inhibitor, whereas four-factor PCC may be a more appropriate first-line option for factor Xa inhibitors. Of note, use of these products for this indication is off-label, and consultation with a hematology service is recommended, if available, and reasonable in the setting of the emergency. Although the current options and data for NOAC reversal are not well researched, new targeted antidotes are on the horizon, with idarucizumab for dabigatran reversal gaining significant attention, having just gained accelerated approval by the FDA on October 16, 2015.\textsuperscript{49}

Antiplatelet Reversal

Although anticoagulants have been reliably linked to ICH, the data are more conflicting on the effects of prior antiplatelet treatment. It has been shown that platelet transfusion within 12 hours of symptom onset is associated with smaller final hemorrhage and even level of independence at 3 months.\(^5\) There are currently ongoing studies evaluating platelet transfusion in patients with ICH on prior antiplatelet therapy, which will hopefully elucidate the topic.

Blood Pressure Management

It is unsurprising that elevated blood pressure is a common presentation in patients with ICH. This presentation can be related to persistent and pre-ICH elevations, as well as stress, pain, and increased ICP. Nonetheless, it is well documented that elevated systolic blood pressure is associated with hematoma expansion, neurological deterioration, and death or dependency after an event.\(^5\)\(^-\)\(^5\)\(^3\) Although the safety and efficacy of systolic blood pressure lowering to 140 mm Hg or less has been well established in the literature,\(^5\)\(^4\)\(^-\)\(^5\)\(^7\) there is only a paucity of data relating to the safety and efficacy of this goal for those presenting with a systolic blood pressure greater than 220 mm Hg. Nonetheless, it may still be reasonable to explore...
aggressive blood pressure lowering in those patients. \textsuperscript{35} Reasonable options for initial blood pressure lowering include bolus doses of labetalol or hydralazine or more aggressive management by a nicardipine or esmolol infusion. \textsuperscript{36}

**Surgical Intervention**

In addition to the medical interventions that can be made, surgical intervention is an option. Surgical interventions typically include clot removal or craniotomy. These procedures are typically reserved for rapidly deteriorating patients and are generally not recommended in early aggressive treatment of the non-rapidly deteriorating patient. \textsuperscript{35}

**Supportive Care**

**Location of Initial Care**

It is recommended that the initial care of the patient with ICH occur in a dedicated stroke unit or an ICU. In fact, care in a dedicated unit has been shown to improve mortality. \textsuperscript{58} Patients require close monitoring, and it is ideal to have staff trained specifically in the care of neurological injury.

**Temperature Control**

One parameter that should be monitored is temperature. A temperature fluctuation in the patient with ICH is a predictor of outcome, and fever is a common occurrence in these patients and may be an indicator of hematoma expansion or increased ICP. \textsuperscript{59} Therefore, treatment of fever in patients with ICH is a reasonable clinical decision. \textsuperscript{55} Although there is a paucity of data to suggest that cooling reduces edema, the treatment is still considered experimental at this time. \textsuperscript{35}
VTE Prophylaxis

Patients presenting with an ICH are also at an increased risk of thromboembolic events, with women and African Americans being at the highest risk; therefore, consideration must be given to prevention of such complications during the patient’s admission. It is generally accepted that these patients should use an intermittent pneumatic compression device in addition to compression stockings for prevention.\textsuperscript{60-62} Although it may seem counterintuitive, these patients may also benefit from prophylaxis with low-molecular-weight or unfractionated heparin. A meta-analysis published in 2011 showed that early use of chemical thromboprophylaxis was associated with a reduction in pulmonary embolism. There was no difference in hematoma enlargement between groups.\textsuperscript{35,63} The ideal timing of initiation of pharmacologic prophylaxis is unclear.

Glucose Management

Glucose monitoring is an important component of post-ICH management. Although clearly defined goals have not so far been established, both hyperglycemia and hypoglycemia are associated with worse outcomes. Therefore, therapy should be initiated to prevent hyperglycemia and hypoglycemia.\textsuperscript{64,65}

Seizure Prophylaxis

Secondary to the neurologic nature of ICH injury, patients are at risk of seizures, and ICH has an early seizure (within 1 week) frequency of about 16%. Although anti-epileptic drugs reduce the number of clinical seizures, this has yet to be associated with improved neurologic outcome or mortality. However, data suggest that prophylaxis with these medications (especially phenytoin) is associated with increased mortality and disability. Therefore, routine use of seizure prophylaxis is not currently recommended and should be used when patient examination indicates a suspicion of seizure.\textsuperscript{35}

LEARNING OBJECTIVES

1. Describe the epidemiology and risk factors of aneurysmal subarachnoid hemorrhage (aSAH).

2. Explain the complex pathophysiological mechanisms of early brain injury and delayed cerebral ischemia.

3. Discuss the clinical presentation of patients with aSAH and clinical severity scores.

4. Outline the predictors of outcome after aSAH.

5. Recognize the common neurological and medical complications associated with aSAH.

6. Develop an evidence-based treatment plan for preventing and treating each neurological and medical complication.
ABBREVIATIONS IN THIS CHAPTER

aSAH  Aneurysmal subarachnoid hemorrhage
CPP  Cerebral perfusion pressure
CSF  Cerebrospinal fluid
DCI  Delayed cerebral ischemia
DVT  Deep venous thrombosis
GCS  Glasgow Coma Scale
ICP  Intracranial pressure
ICU  Intensive care unit
TCD  Transcranial Doppler

INTRODUCTION

Subarachnoid hemorrhage refers to bleeding that occurs in the subarachnoid space, between the pia and the arachnoid membranes, and can be spontaneous or secondary to trauma. The focus of this chapter will be spontaneous subarachnoid hemorrhage, which is caused by the rupture of a saccular aneurysm in 80% of cases. Aneurysmal subarachnoid hemorrhage (aSAH) accounts for about 7% of all strokes and is associated with high morbidity and mortality. The disease course can be prolonged and can be associated with serious neurological and medical complications that compromise patient outcomes. The clinical effects of aSAH are biphasic, consisting of early brain injury as a result of the initial impact of the hemorrhage, followed by several secondary pathophysiological events. As a result, patients are routinely admitted to an intensive care unit (ICU) and are ideally cared for by a multidisciplinary care team.
Epidemiology

The annual incidence of aSAH varies widely in different regions of the world, from 2 to 20 cases per 100,000. Studies from the World Health Organization report an age-adjusted annual incidence of 2 cases per 100,000 population in China to 22.5 cases per 100,000 in Finland. Overall, the incidence is higher in Finland and Japan and lower in South and Central America. In the United States, the incidence is estimated at 14.5 cases per 100,000 annually. This may be an underestimate, however, because up to 15% of patients die before receiving medical care.

The incidence of aSAH is reported to be 1.24 times (95% confidence interval [CI], 1.09–1.42) higher in women than in men and increases with age, with the typical age of onset at 50 years or older. Race and ethnicity also affect aSAH incidence, with African Americans and Hispanics having a higher incidence than white Americans.

Risk Factors

Independent modifiable risk factors include hypertension, smoking, alcohol use, and use of sympathomimetic drugs, whereas nonmodifiable risk factors include sex, age, size of aneurysm, and family history. When assessing risk factors, it is important to consider the risk factors for aneurysm formation and growth together with aSAH.

Cigarette smoking has been identified as an important risk factor for aneurysm formation, growth, and rupture. Hypertension can be considered a significant risk factor for aSAH but may be less of a risk than in other types of stroke. Data on the role of hypertension on aneurysm formation and growth are inconsistent; however, hypertension should be treated for many other reasons, and in doing so, the risk of aSAH may be reduced. If the systolic blood pressure exceeds 130 mm Hg, the risk is twice as high, and if the systolic blood pressure is above 170 mm Hg, the risk is 3 times as high. The role of alcohol use is a less-established risk factor than cigarette
smoking, with several studies showing that excessive alcohol consumption (greater than 150 g/week) increases the risk of aSAH.\textsuperscript{9,10} More traditional cardiovascular risk factors like diabetes and hypercholesterolemia have a less-defined relationship for aSAH or aneurysm formation and growth.

A family history of intracranial aneurysms suggests a genetic component to this disease. Siblings of patients with aSAH have a 6-fold increased risk of developing aSAH, and there is a 3–7 times higher risk in first-degree relatives of patients with aSAH than in the general population.\textsuperscript{12} Familial aneurysms are usually larger at the time of rupture and are more likely located in the middle cerebral artery; also, the age at presentation is typically younger.\textsuperscript{12} Other risk factors for forming intracranial aneurysms include sickle cell disease, $\alpha_2$-antitrypsin deficiency, polycystic kidney disease, and inheritable connective tissue disorders (e.g., fibromuscular dysplasia).

**Outcomes**

Although mortality rates have declined throughout the past 3 decades, aSAH remains a devastating neurological disease. Estimations of current mortality rates show that 10%–15% of patients die before reaching the hospital, whereas 40% die within the first week and 50% die within the first 6 months. Rebleeding also carries a high mortality rate of 51%–80%.\textsuperscript{13} Of those who survive, up to 50% have some degree of cognitive dysfunction long term.\textsuperscript{14} Survivors commonly have deficits in memory, executive function, and language that significantly affect their day-to-day function. These deficits in cognition are further compounded by anxiety, depression, fatigue, and sleep disturbances.\textsuperscript{15} The most important predictive factors for an acute prognosis after aSAH include the following\textsuperscript{16-19}:

- Level of consciousness and neurological grade on admission
- Patient age (younger patients do better)
- Amount of blood on the initial head computed tomography (CT) scan and location of blood (presence of intraventricular
hemorrhage carries a worse prognosis)
- Presence of comorbid conditions and the hospital course
  (e.g., infections, myocardial ischemia, anemia)
- Location of aneurysm (anterior circulation aneurysms carry a
  more favorable prognosis)
- Aneurysm rebleeding
- Global cerebral edema
- Hyperglycemia

The rebleeding rate is 2%–4% within the first 24 hours and 15%–
20% within the first 2 weeks if the aneurysm is not secured and is a
significant cause of poor outcomes early on. Factors associated with
poor outcomes that develop later include cerebral infarction, delayed
cerebral ischemia (DCI), fever, and use of anticonvulsant agents,
particularly phenytoin.16

PATHOPHYSIOLOGY

Aneurysm Formation

The pathogenesis of intracranial aneurysms is complex. Historically,
congenital causes were thought to play a major role in aneurysm
development; however, only 10% of cases appear to be attributable to
genetic/familial causes. The current theory is that aneurysms develop
gradually throughout an individual’s lifetime because of acquired
changes in the intracranial arterial wall. In patients without the
previously discussed risk factors, the prevalence of aneurysms is only
2.3%.20 Inflammation may also play a role in aneurysm formation, with
several inflammatory cytokines being implicated in endothelial injury and
remodeling.21 Inflammation is becoming an attractive therapeutic target
because aspirin may reduce the rate of aneurysm rupture, given its
anti-inflammatory properties; however, more definitive studies are
required.22

Saccular or berry aneurysms account for 80% of aSAH cases and
are specific to intracranial arteries because their walls lack an external elastic lamina and contain a very thin adventitia. Rupture of arteriovenous malformations is the second most identifiable cause of aSAH, accounting for 10% of cases. The remaining cases can result from rupture of these pathologic entities: mycotic aneurysm, angioma, neoplasm, or cortical thrombosis.

The circle of Willis is the most common area in the cerebral circulation for the development of cerebral aneurysms (see Figure 22.1). The bifurcations of these major vessels are particularly vulnerable to aneurysm formation because of hemodynamic factors such as wall sheer stress and mechanical stretch. Most ruptured aneurysms (89%) arise from the anterior circulation. In 25% of cases, aneurysms are present.

Most aneurysms do not rupture according to radiographic and autopsy studies, which report a higher incidence of intracranial saccular aneurysms than of aSAH. The probability of rupture is related to the tension on the artery wall and is directly related to the aneurysm size. Aneurysms with a diameter of 5 mm or less have a 2.5% risk of rupture, whereas 41% of those with a diameter of 6–10 mm have already ruptured on diagnosis. Aneurysms larger than 10 mm in diameter are 5 times more likely to rupture than small aneurysms. The annual risk of rupture for aneurysms less than 10 mm is 0.7%. The exact mechanism for aneurysm rupture is not fully understood, but it may be precipitated in activities that result in a sudden increase in arterial blood pressure (e.g., sneezing, exercise, sexual intercourse) in less than one-third of cases.

**Early Brain Injury**

Early brain injury has been used to describe the mechanisms of acute (first 72 hours) neurological deterioration after aSAH and is the result of physiological derangements such as increased intracranial pressure (ICP), decreased cerebral blood flow, and global cerebral ischemia. These physiologic derangements result in blood-brain barrier dysfunction, inflammation, and oxidative cascades that lead to neuronal
cell death. The consequences can result in death or severe neurological deficits. Although vasospasm is thought to be the main cause of clinical deterioration after aSAH, more recent thinking has focused on the fact that vasospasm is not the only pathophysiological factor contributing to poor patient outcomes. Recently, a study showed an increase in the neuroinflammatory response after aSAH at days 2–3 with no evidence angiographically of vasospasm, and this response was associated with a poor outcome at 3 months. Evidence also suggests that the cascade of events set in motion in early brain injury contributes to the delayed neurological deterioration traditionally attributed to vasospasm. Figure 22.2 describes the complex pathophysiological events after aSAH that lead to early brain injury and DCI.
Figure 22.1 Location of aneurysm responsible for subarachnoid hemorrhage in the “circle of Willis.” Most (85%) saccular aneurysms arise in the vessels that constitute the circle of Willis at the base of the brain. The anterior circulation comprises the anterior cerebral
arteries that are joined by a single anterior communicating artery that is paired with the internal carotid arteries. Most aneurysms are within the anterior circulation. The posterior circulation is composed of the posterior communicating arteries that are paired with the posterior cerebral arteries that originate at the bifurcation of the basilar terminus of the basilar artery.

Early brain injury starts with the initial response of increased ICP because of the blood in the subarachnoid space and sometimes the cerebral ventricle and brain parenchyma. The quantity of the initial bleed drives the degree of ICP elevation the patient experiences. With this increase in ICP, the cerebral perfusion pressure (CPP) decreases, causing cerebral ischemia through a reduction in cerebral blood flow because cerebral autoregulation may be disturbed. The presence of blood and its degraded products in the cerebral ventricles produces obstructive hydrocephalus, which also results in an increase in ICP. As a result, global ischemia may occur, which produces oxidative damage to neural tissue and then neuronal death. Oxidative mediators can also disrupt the blood-brain barrier and lead to the production of cytotoxic cerebral edema, which results in more ischemia.\textsuperscript{27} The global ischemia experienced varies in severity, with about 30\% of patients having necrosis throughout the brain and the remainder, a degree of ischemia not as severe but in which both apoptosis and necrosis may be present. Overall, brain injury occurs from transient global ischemia and from the direct effects of the intracranial blood.

The ischemic insults to the brain after aSAH stimulate several complex pathways that can lead to stimulation of apoptotic mechanisms in the hippocampus, blood-brain barrier, and vasculature, resulting in early brain injury. Some of the proposed different mechanisms for early brain injury include nitric oxide dysregulation, oxidative injury, generation of matrix metalloproteinase-9, modulation of nuclear factor erythroid-2 related factor 2 and antioxidant-response element pathway, interleukin-1 beta activation, vascular endothelial
growth factor, activation of c-Jun N-terminal kinase pathway, mitogen-activation protein kinase, and iron overload. Currently, interventions targeting early brain injury are mainly experimental, but they deserve further investigation because the cerebral infarction that occurs in aSAH not only occurs after vasospasm but also as a result of the physiologic changes that occur with the initial bleed.

Delayed Neurological Deterioration

Neurological worsening that occurs days after aSAH can be ascribed to DCI (see Figure 22.2). Throughout the literature, various terms are used that may be confused as being interchangeable: symptomatic vasospasm, DCI, and angiographic vasospasm. Delayed cerebral ischemia is a clinical syndrome that encompasses symptomatic deterioration in the neurological examination together with radiographic evidence of ischemia or infarction. Not all patients with DCI have angiographic vasospasm, and not all patients with angiographic spasm have DCI. Delayed cerebral ischemia occurs in about 30% of patients 3–14 days after the initial hemorrhage and is the most important cause of mortality and morbidity in the patients who survive the initial bleed.

Angiographic vasospasm occurs within 3–14 days after aneurysm rupture in almost 70% of patients, 30% of whom develop significant global or focal neurological deficits. The severity and duration of vasospasm are related to the thickness, density, location, and persistence of the subarachnoid blood. The most likely mechanism for development is an inflammatory reaction in the blood vessel wall. Extravasated blood and its by-products in the cerebrospinal fluid (CSF) are thought to be responsible for this complication. Many spasmogens such as oxyhemoglobin, histamine, eicosanoids, endothelin, nitrous oxide, and 2-hydroxy-3-methyl glutaryl coenzyme have been implicated in the development of vasospasm. These spasmogenic substances cause endothelial damage and smooth muscle contraction and can result in cerebral hypoperfusion, DCI, and infarction. The true connection between vasospasm and DCI is under question because interventions have shown that significant reductions in angiographic
vasospasm do not improve outcome. Clinical and physiological factors that influence whether angiographic vasospasm causes cerebral infarction include genetic variations (APOE [apolipoprotein E] alleles, polymorphisms of eNOS [endothelial nitric oxide synthase] and plasminogen activator inhibitor-1), epigenetic variations, DNA polymorphisms, cerebral metabolic demand, autoregulation, variations in collateral and anastomotic blood flow, cardiac output, and ICP.

Figure 22.2 Pathophysiology of early brain injury and delayed cerebral ischemia after aSAH. The etiology starts with early brain injury as a result of the initial bleeding event, leading to transient global cerebral ischemia. This process starts a complex cascade of pathophysiological changes leading to secondary brain injury.

aSAH = aneurysmal subarachnoid hemorrhage; BBB = blood-brain barrier; CBF = cerebral blood flow; CBV = cerebral blood volume; CPP = cerebral perfusion pressure; ET-1 = endothelin-A; ICP = intracranial pressure; NO = nitric oxide; NOS = nitric oxide synthase; TF = tissue factor.
Angiographic vasospasm may be associated with DCI, but other pathophysiological factors may also play a role in DCI development such as microthrombosis, cortical spreading ischemia, microcirculatory constriction, and apoptosis. Nimodipine is currently the only pharmacologic agent that has shown an improvement in outcome after aSAH, and it is indicated for use by the U.S. Food and Drug Administration (FDA). In clinical trials, nimodipine did not show a significant improvement in angiographic vasospasm, which led to other theories surrounding the benefit of this agent. It is proposed that nimodipine slightly attenuates vasospasm but also inhibits cortical spreading ischemia and reduces microthrombi through its fibrinolytic activity.

Systemic Effects
The extent of injury after aSAH also affects other organ systems like the heart and lung. There is an increase in sympathetic nervous system activity that can contribute to the development of acute lung injury, pulmonary edema, and cardiac dysfunction (takotsubo cardiomyopathy, stunned myocardium, ECG changes). The most prevalent systemic response that occurs in up to 60% of patients with aSAH is a systemic inflammatory response characterized by increased or decreased body temperature, tachypnea, tachycardia, and leukocytosis or leukopenia.

CARE SETTINGS AND MULTIDISCIPLINARY TEAM
Aneurysmal subarachnoid hemorrhage is a complex disease with a prolonged course that requires expertise from a multidisciplinary team. Ideally, the management of patients with aSAH should take place in a neuro-ICU or an ICU similarly equipped that treats a high volume of patients with aSAH. The available data analyses show that high-volume centers (defined as greater than 60 cases per year) had the best outcomes and that low-volume centers with less than 20 cases per
year had the worst outcomes.\textsuperscript{42,43} The most recent guidelines by both the Neurocritical Care Society (NCS) Multidisciplinary Consensus Conference and the American Heart Association/American Stroke Association (AHA/ASA) recommend that patients with aSAH be treated at high-volume centers and that low-volume hospitals consider early transfer of these patients to high-volume centers.\textsuperscript{44,45} A multidisciplinary neurocritical care team in a specialized neuro-ICU is independently associated with improved hospital discharge disposition for patients with aSAH.\textsuperscript{46} This improved outcome may not be a result of the single addition of any type of personnel; rather, it may be the overall impact of a consistent and organized approach to patient management that contributes to improved outcomes.

\textbf{INITIAL STABILIZATION IN EMERGENCY DEPARTMENT}

\textbf{Clinical Features}

The clinical presentation of aSAH can vary dramatically from what is described as “the worst headache of my life” to coma or death. Often, patients have nausea, vomiting, neck stiffness, and photophobia in addition to the sudden-onset severe headache. With more severe presentations, patients may have an altered level of consciousness with states of confusion, lethargy, or coma. Furthermore, focal neurological deficits such as motor weakness, aphasia, special neglect, or cranial nerve palsies may be present. Commonly, patients may have had a severe headache similar in nature several days before presentation, which has been termed a sentinel bleed.

\textbf{Diagnostic Approaches to aSAH}

The diagnosis of aSAH must be considered when patients present with the classic symptoms; however, because many of the symptoms are nonspecific, the diagnosis is commonly missed on initial presentation to a medical provider.\textsuperscript{47} Because patients who are initially misdiagnosed have a higher rate of complications, an accurate and sensitive workup
must be initiated at presentation.\textsuperscript{48} The sensitivity for noncontrast head CT has been validated and is 98\%–100\% within 12 hours from onset and 93\% at 24 hours.\textsuperscript{49,50} After 3 days, however, the sensitivity decreases to 73\% and after 7 days, to 50\%, which results in a high likelihood of a false-negative study.\textsuperscript{49,50} If the clinical suspicion is high, a lumbar puncture to evaluate for xanthochromia is warranted. This should be done at least 12 hours after the onset of headache for a negative study to be valid because it takes this amount of time for xanthochromia to develop from red blood cell breakdown.\textsuperscript{47} Magnetic resonance imaging (MRI) is up to 100\% sensitive in the detection of aSAH and can be considered as an alternative to lumbar puncture; however, it is not available at many hospitals and is not cost-effective.\textsuperscript{51} For patients in whom the diagnosis of aSAH has not been effectively ruled out, a further imaging study is required. Computed tomography angiography, a high-resolution CT scan of the cerebral arteries that is obtained after intravenous contrast injection, is comparable with the gold standard procedure, digital subtraction angiography of the cerebral blood vessels.\textsuperscript{52} When an aneurysm is not identified in this circumstance, repeat imaging in a delayed fashion after 1–2 weeks is supported, given that an undetected untreated aneurysm has high morbidity and mortality.\textsuperscript{53}

**Clinical Severity Scores**

Many scoring algorithms have been developed with the aim of predicting the outcome and risk of neurological complications after aSAH (Table 22.1). The most widely used clinical scoring systems to predict outcome include the Hunt and Hess score and the World Federation of Neurological Surgeons score. With both scales, the higher the score, the higher the likelihood of a poor outcome.\textsuperscript{54,55} The Hunt and Hess score is an ordinal scale from 1 to 5 that is based on the level of consciousness as well as focal neurological deficits. Patients who score a 1 are asymptomatic or have a mild headache, whereas those who score a 5 are comatose with reflexive motor response only. The World Federation of Neurological Surgeons score is
based on two components: the overall neurological status according to the Glasgow Coma Scale (GCS), range 3–15, and the absence or presence of motor deficits. Patients with a normal GCS of 15 and no neurological deficits are given a score of I, whereas those with a GCS score of 3–6 with or without motor deficits are given a V.

The Fisher grade was developed to predict the risk of cerebral vasospasm after aSAH according to the amount of blood revealed on head CT at presentation. Patients with no hemorrhage or with a hemorrhage of minimal thickness have a very low rate of vasospasm, whereas those with a hemorrhage greater than 1 mm in thickness have a high rate of developing clinical vasospasm and a worse outcome.

MANAGEMENT AND PREVENTION OF NEUROLOGICAL COMPLICATIONS

The primary strategies used in the management of aSAH are to provide initial supportive therapy and to prevent both neurological and medical complications (see Table 22.2 and Table 22.3).

Rebleeding

Recurrent bleeding of an aneurysm after the initial hemorrhage is often fatal, and early measures should be in place to reduce this risk. The highest risk is within the first 24 hours; therefore, treatment of the underlying aneurysm should be completed on an emergency basis. Furthermore, medical management should include therapies aimed at risk reduction, including strict blood pressure control and the consideration of antifibrinolytics. Other important supportive interventions include the use of bed rest, stool softeners to prevent straining, and pain management because pain is associated with a transient elevation in blood pressure, which can increase the risk of rebleeding.

SAH = aneurysmal subarachnoid hemorrhage; DCI = delayed cerebral ischemia.

Strict blood pressure control in the acute phase until the aneurysm is secured is reasonable to reduce the risk of rebleeding. Although no prospective studies show a reduction in rebleeding with aggressive blood pressure control, the consensus guidelines recommend a treatment systolic blood pressure threshold of 160 mm Hg.\textsuperscript{44,45} If antihypertensive therapy is indicated, an intravenous agent that is easily titratable to goal blood pressure and that has minimal negative effects on cerebral hemodynamics should be used.\textsuperscript{58} The use of intermittent bolus doses of antihypertensives such as labetalol may be effective; however, intermittent bolus dosing may lead to significant blood pressure variability. A continuous intravenous infusion such as nicardipine or clevidipine can be titrated more effectively to maintain the blood pressure goal.\textsuperscript{59} Please see Table 22.4 for a comparison of the acute blood pressure–lowering agents that can be used to manage...
blood pressure before securing the aneurysm.

The use of antifibrinolytics (tranexamic acid or amino-caproic acid) in the immediate period after hemorrhage and before treatment of the aneurysm is reasonable; antifibrinolytics should be considered primarily in patients who cannot have the aneurysm secured in a timely manner. Data have been conflicting regarding the effectiveness and safety of these agents; however, much of the debate surrounds the timing and duration of treatment. Patients treated with antifibrinolytic therapy for a prolonged period appear to have an increased risk of DCI. A recent Cochrane analysis does not support the use of antifibrinolytics to reduce the risk of rebleeding; however, this analysis included only one study that limited the use to 72 hours. More recent studies limiting the use of therapy to 72 hours have shown a benefit in reducing the risk of rebleeding from about 10% to 3%. Short-term treatment with antifibrinolytics can be considered, especially for patients who cannot be treated immediately. The definitive prevention for rebleeding is aneurysmal coiling or clipping, and any benefit from antifibrinolytics in SAH is likely to be a temporary measure until the offending aneurysm is secured. Delayed (greater than 48 hours from ictus) or prolonged (greater than 3 days) use of antifibrinolytic agents exposes patients to adverse effects such as cerebral infarction during the time for which the risk of rebleeding is reduced and vasospasm is increased and thus should be avoided.

The key treatment in aSAH is stabilizing the aneurysm to prevent rebleeding. Two approaches can be taken: surgical clipping and endovascular coiling. In endovascular coiling, a catheter is placed in the artery to gain access to the aneurysm, after which platinum coils are placed inside the aneurysm to embolize the aneurysm. Clipping is an invasive surgical intervention whereby a surgical clip is placed over the aneurysm, obliterating it and blocking blood flow into the aneurysm. Long-term controversy exists on which intervention is preferred because both interventions are effective. To date, the International Subarachnoid Aneurysm Trial (ISAT) has been the largest study (more than 2,100 patients) to compare coiling and clipping. The results showed that endovascular coiling was associated with a lower 1-year
mortality rate compared with surgical clipping (absolute risk reduction 7.4%; relative risk reduction 23.9%). However, long-term follow-up showed that rebleeding rates and the need for additional coiling were more frequent in patients treated with intravascular coiling. The risk of death at 5 years was significantly lower in the coiling group. Attempts have been made to identify subgroups of patients for which one approach may be preferred to the other. Most clinicians agree that clipping may be preferred in patients presenting with large (greater than 50 mL) intraparenchymal hematomas and middle cerebral artery aneurysms, whereas endovascular coiling may be considered in older adults (older than 70 years), those presenting with poor-grade aSAH (World Federation of Neurological Surgeons classification IV/V), and those with aneurysms of the basilar tip. Overall, the current guidelines recommend that surgical clipping or coiling be done as early as feasible in most patients to reduce the rate of rebleeding (class I; level of evidence B), and the determination of treatment should be a multidisciplinary decision based on characteristics of the patient and the aneurysm (class I; level of evidence C).

Seizures

Seizures after aSAH are of concern because of their association with early complications, such as rebleeding and poor outcomes. The reported incidence of seizures remains highest at the time of aneurysm rupture, with a rate varying from 4% to 26%. This discrepancy in reported events is partly because of the occurrence of both seizures and seizure-like phenomena, which may be difficult to distinguish, at the time of aneurysm rupture.

After aneurysm treatment, the incidence of seizures appears low and may be related to the method in which the aneurysm was secured, thickness of the subarachnoid clot, aneurysm location, presence of subdural hematoma, and secondary cerebral infarction. The ISAT study reported that the frequency of seizures was 0.65% after hospitalization but before treatment and 2.3% between treatment and discharge. The frequency of seizures after treatment and before
discharge was doubled in patients treated with surgical clipping (3.1%) compared with patients undergoing endovascular treatment (1.5%). In a 14-year follow-up, 10.9% of patients enrolled in ISAT had a seizure. During this period, there was a higher incidence of posttreatment seizures in patients who underwent surgical clipping compared with endovascular coiling (13.6% vs. 8.3%, p=0.014).

Appropriate management of seizures related to aSAH remains an area of debate. Although the use of prophylactic antiepileptic drugs in the setting of aSAH is common, there is a paucity of evidence showing the safety and efficacy of this practice. This has led to highly variable practice between institutions and physicians. Most literature evaluating the use of prophylactic antiepileptic drugs in the setting of aSAH is observational and focuses mainly on phenytoin. One of the first studies published evaluating this area described the early use of a short perioperative course of phenytoin for seizure prophylaxis in low-risk patients. Patients without a history of seizure disorder, cerebral ischemia, parenchymal clot, postoperative hematoma, or concomitant arteriovenous malformation received a phenytoin 900- to 1100-mg load, followed by 300 mg/day for an average of 5.3 days. The overall seizure rate was 5.4% with an average follow-up of 2.4 years, leading the authors to advocate for no more than 7 days of phenytoin for seizure prophylaxis in most patients with aSAH. A retrospective review of 453 patients built on these data by comparing phenytoin prophylaxis (1000-mg loading dose, followed by 300 mg/day) through hospital discharge (average 14 days) to 3 days. This review found a similar incidence of seizures between the two groups during hospitalization (discharge 1.3% vs. 3 days 1.9%, p=0.6) and at follow-up (5.7% vs. 4.6%, p=0.6; follow-up ranged from 3 to 12 months). Of note, few of these studies included a high percentage of patients who were treated with coiling of the aneurysm, so most of the data are from aneurysm clipping.

The use of phenytoin is not without risk because several studies have shown phenytoin to have a negative impact on neurological outcomes. In addition, phenytoin is a significant inhibitor and inducer of many hepatic enzymes, leading to potential drug-drug
Literature regarding the use of alternative antiepileptic drugs for seizure prophylaxis in the setting of aSAH is scarce, with the most support currently for levetiracetam. One retrospective study (n=442) compared short-course levetiracetam (500 mg twice daily; median therapy duration 3.6 days) with extended-duration phenytoin (15- to 20-mg/kg loading dose, followed by maintenance dose; median therapy duration 13.7 days) for seizure prophylaxis after aSAH. The levetiracetam group had a higher incidence of in-hospital seizures (8.3% vs. 3.4%, p=0.03); however, this was driven by the increased incidence of late seizures in the levetiracetam group, which suggests a longer duration of prophylaxis is needed. Levetiracetam was also compared with phenytoin for seizure prophylaxis in a prospective, single-center, randomized trial of patients with severe traumatic brain injury or subarachnoid hemorrhage (n=52; 89% of patients included in the trial had a primary diagnosis of severe traumatic brain injury). Patients received either phenytoin (20 mg/kg load, followed by 5 mg/kg/day) or levetiracetam (20 mg/kg load, followed by 1000 mg twice daily) for 7 days. No difference was observed in seizure occurrence (phenytoin group: 16.7% vs. levetiracetam group 14.7%, p=1.0), and patients in the levetiracetam group had better outcomes in Disability Rating Scale scores and higher Glasgow Outcomes Scale-Extended scores at 3 and 6 months.

The lack of high-quality literature available regarding seizure prophylaxis in this population is reflected in the current guidelines (see Table 22.3). The NCS guidelines recommend against the use of phenytoin for seizure prophylaxis, although they state that the role of other antiepileptic drugs is unclear. Both guidelines state that the use of prophylactic antiepileptic drugs may be considered in the immediate posthemorrhagic period for a short duration (NCS guidelines 3–7 days). A longer duration may be considered for patients with risk factors for a delayed seizure disorder such as a prior seizure or in those who have a seizure after presentation.

Hydrocephalus
Hydrocephalus is a common acute complication of aSAH occurring in about 15%–20% of patients.\textsuperscript{81,82} This complication occurs because of either the obstructed circulation of CSF or the impairment in absorption of CSF that occurs by the arachnoid granulations.\textsuperscript{83} When symptomatic hydrocephalus occurs, the standard treatment is CSF diversion through an external ventricular drain. Placement of this type of drain allows for both the drainage of CSF and the measurement of ICP. When significant intraventricular blood is present, aggressive treatment with CSF diversion and drainage of the ventricular clot may reduce the risk of cerebral vasospasm.\textsuperscript{84} The alteration in CSF flow dynamics or reabsorption can be transient, during which the drain can be removed; however, it can also be permanent, necessitating the placement of a permanent shunt.

In patients with an altered level of consciousness, the evaluation for hydrocephalus can be more difficult. An alteration in the level of consciousness is the most common symptom of hydrocephalus; therefore, a combination of clinical judgment and imaging are required to determine whether CSF diversion and ICP monitoring is indicated. Commonly, a GCS score of 8 or lower is used to determine when a patient requires ICP monitoring, which can be done through an external ventricular drain or an intraparenchymal ICP monitor. In those with hydrocephalus on head CT and a clinical picture consistent with symptomatic hydrocephalus, CSF diversion is warranted regardless of the GCS score.

When ICP monitoring is used, the goal is to maintain the ICP within a normal range and to ensure adequate cerebral perfusion. The CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP). The pressure differential, which is what drives perfusion of the brain, is termed the CPP. The goals are to maintain the ICP less than 20 mm Hg and the CPP greater than 60 mm Hg. Often, vasopressors (phenylephrine or norepinephrine) are required to increase the MAP or hyperosmolar therapy (mannitol or hypertonic saline) is used to decrease the ICP, both of which lead to an increase in the CPP.

Intracranial hypertension is defined as a sustained (more than 5 minutes) elevation of ICP greater than 20 mm Hg. Please see the
article titled “Emergency Neurological Life Support: Intracranial Hypertension and Herniation” for a tiered treatment protocol.  

**DELAYED CEREBRAL ISCHEMIA**

Cerebral vasospasm has traditionally been regarded as the cause of DCI, which occurs after aSAH and leads to cerebral infarction and poor neurological outcomes. However, data from more recent studies argue against a pure focus on vasospasm as the sole cause of DCI. Research is now intensifying on methods for intervention in the early brain injury pathophysiological process, which also contributes to DCI. Narrowing of the cerebral arteries through vasospasm resulting in a reduction in cerebral blood flow may lead to ischemia and infarction. About two-thirds of patients may develop angiographic evidence of vaso-spasm, although only 20%–30% have clinical symptoms. In up to 25% of patients, the delayed infarcts revealed on CT scans are not located in the vascular territory of the spastic artery, or they occur in patients who develop vaso-spasm. The predictive value of radiographic vasospasm for DCI is only about 67%. More recent studies using perfusion imaging methods now suggest that only severe vasospasm with at least a 50% luminal narrowing produces sufficient reductions in cerebral blood flow to cause symptomatic ischemia. Studies have tried to predict the patients more likely to develop vasospasm after aSAH. The strongest risk factor appears to be the volume of subarachnoid clot present, with patients having larger clot volumes being at highest risk. Several other risk factors have also been shown to be predictive of vasospasm, including clinical grade on admission, history of cigarette smoking, history of hypertension, and cocaine use.

**Nomenclature**

Many terms are used somewhat interchangeably in the literature when describing delayed neurological deficits. As previously discussed, many investigators use the terms vasospasm and DCI interchangeably,
making it difficult to evaluate treatments and associated outcomes from research studies. Cerebral vasospasm can be defined as the delayed narrowing of the large arteries within the basal cisterns, which may be associated with clinical or radiographic signs of ischemia in the areas of the brain supplied by the spastic artery. Delayed cerebral ischemia is an umbrella term in the literature that encompasses several clinical entities, including symptomatic vasospasm, delayed ischemic neurological deficit, and asymptomatic delayed cerebral infarction. Not all patients who develop vasospasm develop DCI. Delayed ischemic neurological deficit is a much broader term that includes delayed neurological deficits that occur with or without angiographic vasospasm. Ultimately, DCI is a clinical diagnosis of exclusion that may be difficult to recognize in patients with poor clinical grade aSAH. In 2010, a consensus statement by a multidisciplinary panel proposed new definitions for clinical deterioration caused by DCI and cerebral infarction after aSAH that were further supported by the 2011 NCS consensus guidelines. Overall both consensus groups advocated for a separation of DCI from vasospasm after aSAH.

- DCI = the occurrence of focal neurological impairment (e.g., hemiparesis, aphasia, apraxia, neglect) or a decrease of at least two points on the GCS (either the total scale or one component of the scale). This should last for at least 1 hour, not be apparent immediately after the aneurysm occlusion, and not be attributed to other causes.

- Cerebral infarction = the presence of cerebral infarction by CT or MRI within 6 weeks after aSAH, not present between 24 and 48 hours after early occlusions, and not attributable to other causes such as surgical clipping or endovascular treatment.

**Measuring and Monitoring Cerebral Vasospasm**

The easiest form of vasospasm monitoring involves a vigilant clinical examination. Frequent neurological examinations should be done to establish each patient’s baseline neurologic status and to detect any
changes. Newly identified deficits should be worked up immediately to rule out other causes such as hydrocephalus, seizures, and metabolic abnormalities. Although clinical examination can detect subtle changes in patients with low-grade aSAH, these same changes may not be apparent in a patient who is comatose; therefore, clinical examination alone cannot be used to screen for vasospasm.

Transcranial Doppler (TCD) monitoring was introduced in the 1980s as a less-invasive approach for monitoring cerebral vasospasm and has become a mainstay of vasospasm monitoring in the ICU at many centers. This provides an indirect measure of the vessel diameter by measuring cerebral blood flow velocity. When the proximal cerebral arteries narrow, the velocity of blood flow in those arteries increases and can be detectable by TCD. Absolute velocity of blood flow in the middle cerebral artery shows a strong correlation with the lack or presence of vasospasm when it is low (less than 120 cm/second is low risk for vasospasm) or very high (greater than 200 cm/second is high risk for vasospasm) but does not correlate well in the intermediate range.\textsuperscript{44} The Lindegaard ratio is also predictive of vasospasm and is the middle cerebral artery velocity compared with the velocity in the proximal extra-cranial internal carotid artery ($V_{\text{MCA}}/V_{\text{ICA}}$). A value greater than 3 is consistent with vasospasm.\textsuperscript{96} The disadvantage of this approach is the high interrater variability that is dependent on the operator. In addition, many patients may have dense temporal bone windows that prohibit an accurate measurement, and it is inadequate to identify spasm of more distal arteries. Even with these limitations, however, this tool can be used in the ICU to evaluate trends and complement the clinical examination.

Imaging with perfusion methods such as CT, MRI, and/or positron emission tomography is being used to screen and confirm vasospasm and DCI. These perfusion studies can be combined with noninvasive arteriography to acquire more complete information. Computed tomography angiography is correlated with conventional angiography for large artery narrowing and can be used as a screening tool.\textsuperscript{45} Computed tomography perfusion imaging provides a measure of tissue perfusion. Severe vasospasm is associated with absolute cerebral
blood flows of less than 25 mL/100 g/minute and mean transit times greater than 6.4 seconds or 20% higher than average. The current consensus recommendations suggest that a mean transient time greater than 6.4 seconds on perfusion imaging is additive to CT angiography for predicting DCI. Serial use of these techniques can be limited by cumulative radiation exposure, higher cost, lower availability, and the need for patients to be admitted or transported to centers with this imaging capability.

The gold standard diagnostic method for identifying vasospasm is digital subtraction angiography, which is invasive and expensive and carries the risk of other complications. The serious complication rate is 1%–2% and includes risk of the anesthetic regimen, puncture site complications, contrast nephropathy, allergic reactions, embolic or thrombotic strokes, perforation of the cerebral artery, and intracranial hemorrhage. The advantage of angiography is that it provides the opportunity to treat vasospasm by endovascular approaches; however, using this invasive approach is not appropriate for surveillance monitoring of vasospasm.

Other tools can be used in the ICU to evaluate the physiologic impact of vasospasm, including electroencephalogram, brain tissue oxygen monitoring, and cerebral microdialysis. Electroencephalography has been used to detect reversible cerebral ischemia since the 1970s, and specific patterns have now been correlated with vasospasm. Continuous quantitative electroencephalogram monitoring that focuses on the ratio of fast alpha activity and slow delta activity, alpha variability, and the alpha/delta ratio may precede clinical signs of cerebral ischemia. Relative decreased alpha variability precedes clinical diagnosis of vasospasm by 3 days. Microdialysis may provide a modality for assessing bedside comparisons of neurochemical changes with the patient’s neurological examination. Lactate and glutamate are sensitive markers of impending cerebral ischemia. Brain tissue oxygenation, thermal diffusion cerebral blood flow, and near-infrared spectroscopy have also been used to monitor patients with aSAH with some success, although the value of these approaches is currently unknown. The NCS
published consensus statements on multimodality monitoring that provide a more comprehensive review of these monitoring approaches.\textsuperscript{103}

**Prevention Strategies**

**Calcium Channel Blockers**

The only pharmacologic intervention that improves outcome after aSAH is the calcium channel antagonist, nimodipine.\textsuperscript{104} Nimodipine is a dihydropyridine calcium channel blocker that shows cerebral vascular selectivity by preferentially dilating cerebral blood vessels to a greater degree than the peripheral and coronary vasculature.\textsuperscript{105} Nimodipine has become the standard of care in the United States, according to a clinical trial published in 1983 in which 13\% of patients who were randomized to the placebo group had severe neurologic deficits compared with 1.7\% of patients randomized to nimodipine.\textsuperscript{106} A larger trial showed reductions of 34\% in ischemic stroke and 40\% in poor outcome at 3 months in patients treated with nimodipine compared with placebo.\textsuperscript{107} A subsequent meta-analysis that evaluated nine prospective randomized trials including 1,514 patients showed a significantly reduced incidence of delayed neurological deficits by 38\% (odds ratio [OR] 0.62; 95\% CI, 0.5–0.78) and cerebral infarcts by 48\% (OR 0.52; 95\% CI, 0.41–0.66).\textsuperscript{108}

Originally, it was hypothesized that the benefit from nimodipine was related to a reduction in vasospasm; however, clinical trials did not show a reduction in vasospasm, even while showing an overall improvement in outcome. Clinical trials that have shown the benefit of enteral nimodipine in patients with aSAH used a dose of 60 mg every 4 hours for 21 days. The most common adverse effect is hypotension, which is reported to occur in about 7.7\% of patients. This can be a serious concern because hemodynamic lability is independently associated with death or severe disability after aSAH.\textsuperscript{100} Avoiding blood pressure fluctuations is key in the management of these patients, so alterations in the dosing strategy of nimodipine (30 mg every 2
hours) have been suggested in patients who have hypotension, but this has not been evaluated in clinical trials. Nimodipine has also been shown to be cost-effective, given that it increased patient life-years at a very low incremental cost.\textsuperscript{109} The two guidelines recommend that oral nimodipine (60 mg every 4 hours) be given for 21 days after aSAH.\textsuperscript{44,45} Common practice in patients with a good Hunt and Hess grade aSAH is to discontinue nimodipine as patients are discharged from the hospital, provided there have been no complications from the aSAH or intervention. This practice is not based on evidence, but only on the clinical knowledge that patients with good Hunt and Hess grades are less likely to develop DCI beyond post-aSAH day 10. Similarly, if hypotension is too pervasive, nimodipine may have to be held in an effort to support cerebral perfusion, but this is not based on evidence.

Some serious drug errors have been reported when oral nimodipine is administered intravenously instead of through a nasogastric tube when patients are unable to swallow the capsule. The drug comes with instructions for making a hole in both ends of the capsule with a standard 18-gauge needle for removing the contents with a syringe and then administering through the nasogastric tube. Because these needles do not fit on an oral syringe, an intravenous syringe is used, which has resulted in intravenous administration. Intravenous administration can result in cardiac arrest, dramatic drops in blood pressure, or other cardiovascular adverse events. The FDA issued a drug safety communication in 2010, for which it reported 25 intravenous nimodipine-prescribing or administration errors, where four of the patients died and five had near-death events.\textsuperscript{110} In 2013, the FDA approved a new oral nimodipine solution in an effort to reduce drug errors because this dosage form eliminated the need for needle extraction of nimodipine from the capsules.\textsuperscript{111} There are also potentials for drug interactions between nimodipine and strong inhibitors and inducers of cytochrome P450 (CYP) 3A4. The clinical significance of these drug interactions is the possibility of significant hypotension when administered with CYP3A4 inhibitors and lack of effectiveness when coadministered with CYP3A4 inducers.

The future direction for non-ental delivery of nimodipine compared
with enteral nimodipine is currently being investigated in clinical trials. EG-1962 is a novel polymeric nimodipine microparticle that is administered directly into the cerebral ventricles and provides sustained drug exposure throughout 21 days. EG-1962 uses a programmable, bio-degradable polymer-based development platform known as Precisa. This delivery system allows for targeted drug delivery to the site of injury to provide sustained drug exposure while avoiding systemic toxicities. This site-specific delivery of nimodipine microparticles reduces angiographic vasospasm after aSAH in dogs.\textsuperscript{112} EG-1962 is currently being evaluated in a phase I/II study, NEWTON (Nimodipine Microparticles to Enhance Recovery While Reducing Toxicity After Subarachnoid Hemorrhage), for safety, tolerability and pharmacokinetic properties.\textsuperscript{113,114}

Nicardipine is another calcium channel blocker that has been evaluated for prophylactic use after aSAH. Intravenous nicardipine (0.15 mg/kg/hour for up to 14 days) was compared with placebo. In contrast to the results reported for nimodipine, nicardipine was associated with lower symptomatic vasospasm but was not associated with improvement in neurological outcome at 3 months. Hypotension, the main concern with the use of intravenous nicardipine, occurred in 34.5\% of nicardipine-treated patients compared with 17.5\% of placebo-treated patients. The potential positive effect on outcome may have been negated by the 3\% incidence of life-threatening hypotension that developed.\textsuperscript{115,116}

**Statins**

Statins have generated much interest for the prevention of vasospasm after aSAH because of their pleiotropic effects, which include anti-inflammatory properties, up-regulation of endothelial nitric oxide synthase, anti-adhesive effects on endothelium, amelioration of glutamate-mediated excitotoxicity, and inhibition of platelet aggregation.\textsuperscript{117,118} Because of strong experimental evidence, several studies examined the clinical effect of simvastatin and pravastatin for prevention of vasospasm and DCI. The primary difference between
these statins is that simvastatin has a higher affinity for hydroxymethylglutaryl coenzyme A reductase and is more lipophilic than pravastatin, so it has higher blood-brain barrier penetration.\textsuperscript{119} The results of these studies were critically appraised in two meta-analyses that included four published randomized trials with a total of 190 patients.\textsuperscript{95,120} Simvastatin 80 mg was used in three of the four studies, and pravastatin 40 mg was used in the other study. There was no statistical difference in TCD-detected vasospasm, incidence of DCI, or neurologic outcomes between statin treatment and placebo. The other meta-analysis included these four trials together with two unpublished randomized trials and five observational studies.\textsuperscript{120} Similar to the previous meta-analysis, there was no significant difference in the incidence of DCI. The results of these meta-analyses should be viewed cautiously because the definitions of DCI were inconsistent.

Atorvastatin 40 mg/day for 21 days was studied in 142 patients to evaluate whether this statin could reduce vasospasm-induced ischemia by measuring serum S100B (biomarker for cerebral ischemia) and ischemic lesion volume by CT. Atorvastatin reduced the incidence of cerebral vasospasm, severity of vasospasm, volume of ischemia, and serum S100B concentrations, but there were no differences in clinical outcomes at 1 year.\textsuperscript{121}

The STASH study (Simvastatin in Aneurysmal Subarachnoid Hemorrhage), a phase III randomized trial of 803 patients that compared simvastatin 40 mg with placebo for up to 21 days, was recently published.\textsuperscript{122} Despite showing no safety concerns, this trial failed to show any short- or long-term benefit in outcome, and the investigators concluded that simvastatin should not be routinely used during the acute stages. Several experimental and clinical studies suggest that sudden withdrawal of statins can suppress endothelial nitric oxide production, leading to a higher risk of hemorrhage and vaso-spasm.\textsuperscript{123,124} The current guidelines state that statins may be initiated in statin-naive patients for reducing DCI after aSAH, but these were published before the STASH results; therefore, statins should not be used in statin-naive patients. However, the guidelines do mention continuing patients on statins if they were receiving statins before
Magnesium

Magnesium is a noncompetitive calcium antagonist and is thought to result in smooth muscle relaxation and vessel dilation. Magnesium may also have neuroprotective properties because it decreases glutamate release and reduces calcium entry into cells. Hypomagnesemia occurs in more than 50% of patients with aSAH and is associated with poor outcome and a predictor of DCI. Several clinical trials have investigated the effects of magnesium after aSAH. The first phase III randomized controlled trial enrolled 327 patients within 48 hours of aSAH to either magnesium 20 mmol (5 g) over 30 minutes, followed by an infusion of 80 mmol (20 g)/day for up to 14 days posthemorrhage, or placebo (0.9% sodium chloride). The magnesium infusion was adjusted to achieve a magnesium concentration twice the patient’s baseline up to a maximum of 2.5 mmol/L. There were no significant differences in 6-month outcomes or in the percentage of patients with clinical vasospasm. The MASH-2 (Magnesium for Aneurysmal Subarachnoid Hemorrhage) study is another phase III randomized placebo-controlled trial of 1,204 patients that did not find significant benefit of intravenous magnesium infusion on favorable outcome. The investigators of this trial also completed a meta-analysis and confirmed the lack of benefit of magnesium after aSAH.

Magnesium was administered intravenously in these clinical trials; however, this route of administration does not result in a significant increase in CSF magnesium values, even if the serum magnesium level is increased by 50% or more. Direct administration of magnesium into the basal cisterns may be a more effective approach, although there are currently no ongoing clinical trials investigating magnesium after aSAH. Intravenous administration of magnesium is not currently recommended. However, hypomagnesemia should be avoided.

Clearance of Subarachnoid Spaces
Because the breakdown by-product of the subarachnoid clot is believed to play a key role in the development of vasospasm and DCI, removal of the hemorrhage would appear to be a rational preventive strategy. Some evidence suggests that subarachnoid clot removal achieved by way of intracisternal injections of recombinant tissue plasminogen activator reduces the risk of vasospasm. The recombinant tissue plasminogen activator is usually administered at the time of aneurysm clipping, and because endovascular approaches to aneurysm stabilization are increasingly being used, this approach is not practical for all patients. In addition, the results appear to be inconclusive, and this approach can increase the risk of intracerebral hemorrhage. Currently, the use of intracisternal thrombolytics cannot be recommended.

Intraventricular administration of thrombolytic agents has been investigated as a method for preventing the development of vasospasm. A meta-analysis of five trials that included 465 patients showed significant reductions in the development of vasospasm and DCI. The results of this meta-analysis should be viewed cautiously, given that there were considerable differences in the study methodology of the trials included in the meta-analysis; as such, routine use cannot be currently recommended.

The use of lumbar drains is another approach for clearing subarachnoid blood. A current clinical trial is investigating the benefit of this approach (EARLYDRAIN).

**Endothelin-1 Antagonist**

Endothelin-1 is a 21-amino acid peptide and one of the most potent vasoconstrictors produced in endothelial cells on stimulation by ischemia. It has been suggested that endothelin-1 contributes to an imbalance in vasoconstriction and vasodilation during aSAH. Endothelin-1 can be found in high concentrations in the CSF on day 5 post-ictus, and it corresponds with increased cerebral blood flow velocity. Clazosentan is a selective endothelin-A receptor antagonist that decreases and reverses cerebral vasospasm in experimental aSAH.
The CONSCIOUS-1 (Clazosentan to Overcome Neurological Ischemia and Infarct Occurring After Subarachnoid Hemorrhage) trial showed significant dose-dependent effects on the angiographic incidence of vasospasm with a 65% reduction at the highest dose. The phase III trial, CONSCIOUS-2, was designed to target patients at highest risk of vasospasm and DCI, such as those with substantial blood clot thickness who had undergone surgical clipping. The results of the CONSCIOUS-2 trial showed that clazosentan at 5 mg/hour had no significant effect on mortality, vasospasm-related morbidity, or functional outcome. Pulmonary complications, anemia, and hypotension were more common in the patients who received clazosentan. A similar study of patients who were treated with coiling (CONSCIOUS-3) was stopped early after 577 of the 1,500 patients were enrolled. The results of CONSCIOUS-3 showed findings similar to CONSCIOUS-2 for the 5-mg/hour dose; however, the 15-mg/hour doses significantly reduced vasospasm-related morbidity and all-cause mortality but did not lead to improved outcomes at week 12. The CONSCIOUS-2 and CONSCIOUS-3 trials have raised questions regarding the efficacy of endothelin-1 antagonists in preventing vasospasm; however, the possibility remains that these agents have clinical utility as part of a complex treatment regimen for aSAH.

Treatment Strategies

Hemodynamic and Fluid Goals

Hemodynamic therapy known as triple-H therapy has been a popular approach to managing symptomatic vasospasm in patients who have secured aneurysms, despite the moderate quality of evidence supporting this intervention. Triple-H refers to hypervolemia (central venous pressures 10–12 mm Hg), hypertension (systolic blood pressure 180–220 mm Hg), and hemodilution (hematocrit 30%–35%). The rationale for this therapy is for maintaining high circulating blood volume, increased CPPs, and decreased blood viscosity that will enhance cerebral blood flow in the face of vasoconstriction. There is
currently no supportive evidence from randomized controlled trials that triple-H therapy or its separate components improve cerebral blood flow or clinical outcome in patients with aSAH. The role of triple-H therapy has also been investigated as a prophylactic approach to prevent DCI, with the data showing no benefit and a higher risk of serious adverse effects and death; thus, this approach should be reserved for managing patients with symptomatic vasospasm.

Hemodilution is the most controversial component of triple-H therapy. Although cerebral blood flow increases with a decreasing hematocrit, this approach is also associated with decreased oxygen-carrying capacity and increased volume of ischemic areas of the brain. Higher hemoglobin values are associated with decreased rates of cerebral infarction, poor outcome, and death after aSAH. However, blood transfusions are associated with increased rates of angiographic vasospasm, cerebral ischemia, and worse functional outcomes. There are no convincing data to support an ideal hematocrit; thus, induced hemodilution to achieve a lower hemoglobin or hematocrit to improve blood rheology should be avoided. The current guidelines recommend maintaining hemoglobin concentrations of greater than 8–10 g/dL with packed red cells, although higher thresholds may be appropriate in patients at high risk of DCI. Transfusion with packed red blood cells, however, is not without risk, and a recent retrospective cohort study reported that transfusion with red cells was independently associated with increased mortality in patients with aSAH.

Hypovolemia, which can commonly occur after aSAH, should be avoided because it is associated with worse clinical outcomes. Hypovolemia appears to be a cumulative process and is more prevalent 6–72 hours after aSAH for patients who undergo surgical intervention. Prophylactic hypervolemia does not improve cerebral blood flow or prevent symptomatic vasospasm or DCI and is associated with increased risk of cardiopulmonary complications because of the fluid overload. A recent survey showed that medical centers without a dedicated neuro-ICU are more likely to use prophylactic hypervolemia. The approach to intravascular volume
management should target euvolemia with isotonic crystalloids rather than prophylactic hypervolemia.\textsuperscript{44,45}

The choice of fluid for use in aSAH is typically isotonic crystalloids, which is specifically mentioned in the guidelines. However, other fluid choices have been assessed in patients with aSAH. Hypertonic saline has not been part of the traditional regimen for triple-H therapy, although this fluid can be commonly used for the reduction of ICP and may have clinical benefits in patients with poor-grade aSAH. A prospective study administered a 2-mL/kg infusion of 23.4% sodium chloride over 10–30 minutes to 44 patients with poor-grade aSAH and showed that hypertonic saline increased systemic blood pressure, reduced ICP, and improved cerebral blood flow, cerebral oxygenation, and brain tissue pH. The effects lasted 2–4 hours after administration. Although these data evaluations are limited, hypertonic saline may be an alternative fluid for use in patients with poor-grade aSAH.\textsuperscript{157}

Albumin is another fluid currently being investigated because it is believed to possess neuroprotective properties through several mechanisms, including increasing serum oncotic pressure, improving microcirculatory blood flow, decreasing the inflammatory response, and free radical scavenging properties.\textsuperscript{158} Many of the triple-H regimens evaluated in the literature included albumin as part of their regimen, but there is no good study comparing albumin with crystalloids. A retrospective evaluation of high doses of 25% human albumin used to increase the central venous pressure above 8 mm Hg reported an association with improved outcomes and reduced costs in patients with aSAH.\textsuperscript{159} A phase I dose-escalation study evaluated the safety and efficacy of 25% albumin in doses of 0.625, 1.25, 1.875, and 2.5 g/kg/day for up to 7 days.\textsuperscript{160} Doses up to 1.25 g/kg/day were well tolerated, but the study was terminated early once the dose reached 1.875 g/kg/day because of the development of pulmonary edema. Albumin in Subarachnoid Hemorrhage (ALISAH) II, a phase III randomized placebo-controlled trial powered to test the efficacy of albumin, is planned. Until the results of this study are complete, it is not recommended to routinely use albumin in the management of these patients because patients with traumatic brain injury have shown
increased mortality with the administration of albumin.\textsuperscript{161} However, a recent survey reported that almost one-half (45.9\%) of the respondents commonly administer albumin to their patients with aSAH, but they also acknowledged the need for a randomized clinical trial.\textsuperscript{162}

Although prophylactic hypervolemia is no longer recommended, this approach is still commonly used for the treatment of cerebral vasospasm, though even in this setting, the safety and efficacy of hypervolemia are being reconsidered. In a study of 16 patients with severe vasospasm documented with angiography, the impact of hypervolemia (1,000 mL/day colloid plus 3,740 mL/day crystalloid; mean central venous pressure increase from 5.4 cm H\textsubscript{2}O to 7.4 cm H\textsubscript{2}O), induced hypertension with phenylephrine (MAP increase from 102 mm Hg to 132 mm Hg), or enhanced cardiac output with dobutamine (mean cardiac index increased from 4.1 L/minute/m\textsuperscript{2} to 5 L/minute/m\textsuperscript{2}) was compared using cerebral blood flow as the outcome measurement. Improvements in cerebral blood flow were only observed in patients who received phenylephrine or dobutamine.\textsuperscript{163} Similar results were reported in an observational study of 45 patients wherein induced hypertension increased brain tissue oxygenation in 90\% of patients with an 8\% complication rate, whereas hypervolemia was only effective in 12\% of patients but had a 53\% complication rate.\textsuperscript{164} The role of hypervolemia as a single component of triple-H therapy does not appear to be supported by these small studies. The NCS consensus recommendations suggest considering a saline bolus to increase cerebral blood flow in areas of ischemia as a prelude to other interventions, like induced hypertension.\textsuperscript{45}

Case series have linked induced hypertension with improved neurological improvement and increased cerebral blood flow, especially in patients with angiographic vasospasm or in brain regions that are hypoperfused.\textsuperscript{165-168} Administering vasoactive agents produces a sustained increase in systemic blood pressure that results in improved CPP, cerebral blood flow, and cerebral tissue oxygenation. In clinical studies, induced hypertension was more effective at improving cerebral oxygenation than aggressive hypervolemia.\textsuperscript{164,169} Induced hypertension improves regional cerebral blood flow and brain tissue oxygenation, but
these benefits disappear after induction of hypervolemia. A computational model approach evaluated the effect of hypertension and hemodilution in managing vasospasm. This study found that in cases of severe vasospasm, the systemic blood pressure should be increased in order to reverse vasospasm. Any decreases in hematocrit had minimal impact on cerebral blood flow in a constricted vessel. Two systematic reviews have been published assessing the different components of triple-H therapy. The large heterogeneity in interventions and populations studied prohibited conducting a meta-analysis. Hypervolemia did not appear to be superior to normovolemia, but hypervolemia was associated with more adverse effects. Hemodilution was not associated with a change in cerebral blood flow, and hypertension was associated with higher cerebral blood flow, regardless of the volume status.

Several vasopressors can be used to induce hypertension, including phenylephrine, norepinephrine, and dopamine. In a prospective case series, the use of high-dose phenylephrine had an acceptable safety profile. There are no studies comparing the effect of different agents on cerebral blood flow. Both phenylephrine and norepinephrine are equally used to induce hypertension. Vasopressin is an effective vasopressor agent but is not routinely used in patients with aSAH because of its potential to exacerbate the hyponatremia that can occur in these patients. When vasopressin (0.01–0.04 units/minute) was added to maximal phenylephrine therapy (4–5 mcg/kg/minute) in patients with clinically symptomatic vasospasm, vasopressin was effective in reducing the phenylephrine dosage without reducing serum sodium concentrations or causing detrimental effects on cerebral perfusion or worsening vasospasm. Different approaches with respect to defining the blood pressure targets are used in clinical practice. Some clinicians target a percent increase from baseline blood pressure, whereas others target an arbitrary number. Pressure should be increased in a stepwise fashion, as guided by an assessment of the neurological examination, neuromonitoring, or radiological evidence of improved perfusion.

Cardiac output augmentation is an alternative method for increasing
In addition to treatment of vasospasm, patients with aSAH may have reduced cardiac output because of “stunned myocardium.” An alternative to induced hypertension is the use of inotrophic agents like milrinone or dobutamine to induce a hyperdynamic state. One concern with routine use of these agents is the potential to lower blood pressure. Milrinone may be more potent than dobutamine in increasing cardiac output and is more effective in patients with normal vascular resistance and normal blood pressure yet reduced systolic function. Dobutamine may be a preferred option when vascular resistance or blood pressure is reduced. Inotropic agents may be useful in patients who lack response to induced hyper-tension or have poor cardiac function, but these agents cannot be recommended for prophylactic administration.

Volume status should be routinely monitored in these patients. Although a target central venous pressure of 8 mm Hg or greater has been recommended, it is important to understand the lack of reliability of central venous pressure in estimating intravascular volume; therefore, the approach must be individualized. Goal-directed hemodynamic management using PiCCO has been successfully used in patients with aSAH. The specific targets that have been suggested include the following:

- Cardiac index greater than 3.0 L/minute/m$^2$
- Global end-diastolic volume index equal to 700–900 mL/m$^2$
- Extravascular lung water index less than 14 mL/kg

Larger randomized controlled trials are needed to validate the usefulness of goal-directed hemodynamic monitoring in patients with aSAH.

The current clinical guidelines recommend maintaining euvolemma and inducing hypertension in patients with DCI, except in those who have elevated blood pressure at baseline or have comorbid cardiac disease, which precludes its use. In patients with preexisting cardiac disease and older adults, the risk of complications with hypervolemic/hypertensive therapy is increased; risks include cardiac
failure, pulmonary edema, cerebral edema, and elevated ICP.\textsuperscript{171}

**Locally Administered Pharmacologic Agents**

Targeted delivery of pharmacologic agents through intra-arterial, intraventricular, or intrathecal administration is a method for treating cerebral vasospasm. It is important to evaluate the products directly administered into the central nervous system (CNS) and assess the potential risk of the diluent and other excipients that are contained in the product.\textsuperscript{176} Papaverine is a vasodilator agent that preferentially vasodilates cerebral and coronary vascular smooth muscle. Intra-arterial administration of papaverine (150–600 mg) has shown success in treating cerebral vasospasm in published reports of clinical experience.\textsuperscript{177-183} The limitation with the use of papaverine is the potential for the development of neurotoxicity because of altered mitochondrial cellular respiration with high exposure.\textsuperscript{184} Other adverse events include increased ICP, hemiplegia, seizures, agitation, altered mental status, and hypotension.\textsuperscript{185} Because of these significant safety concerns, papaverine is no longer recommended.

Nicardipine has shown promise when administered by intra-arterial, intrathecal, or intraventricular routes of administration for treating cerebral vasospasm.\textsuperscript{186-190} Intra-arterial administration involves diluting intravenous nicardipine with 0.9% sodium chloride to a concentration of 0.1 mg/mL and administering in 1-mL aliquots through the microcatheter to a maximum of 5 mg per vessel. Nicardipine is effective at inducing vasodilation and reducing mean peak systolic velocities on TCD from pretreatment for 4 days after the infusion. Overall, neurologic improvement was reported in 42% of patients.\textsuperscript{186} Intraventricular administration of nicardipine is an attractive treatment option because it can be administered in the ICU and avoids transport of the patient to the angiography suite. The evidence for this treatment approach is limited to a small case series of eight patients in which nicardipine 4 mg every 12 hours for 5–17 days was administered through the intraventricular catheter. The drug was well tolerated, and seven of the eight patients had good functional outcomes.\textsuperscript{188} There are
several other more recent studies, two of which report a significant and sustained reduction in mean cerebral blood flow velocity after intraventricular nicardipine; however, neither study was powered for clinical outcomes.\textsuperscript{191,192}

Verapamil is another calcium channel antagonist that has been used by way of intra-arterial administration for treating cerebral vasospasm. The published data are from retrospective evaluations in which verapamil was administered at dosages of 25–369 mg per vessel by continuous infusion.\textsuperscript{193-196} Verapamil was effective in reversing vasospasm, but close hemodynamic monitoring is advised because the most common complications include hypotension and bradycardia.

Sodium nitroprusside is another vasodilating agent that has been administered by the intraventricular route. In a prospective study of 25 patients with aSAH, nitroprusside 4 mg/mL was given in escalating doses (8–30 mg) and frequency according to mean blood flow velocity on TCD. An improvement in blood flow velocity was reported, together with hypotension and vomiting.\textsuperscript{197}

Intra-arterial milrinone has also been used to treat cerebral vasospasm.\textsuperscript{198-200} Milrinone is a bipyridine inotropic vasodilator that inhibits peak III cyclic adenosine monophosphate phosphodiesterase isozyme. Combining intra-arterial milrinone (8 mg over 30 minutes repeated up to a maximum of 24 mg) with intravenous milrinone 0.5–1.5 mcg/kg/minute until day 14 after the initial bleed was safe and effective for reversing cerebral vasospasm and was usually well tolerated.\textsuperscript{199}

Local administration of all the agents discussed provides a more targeted approach for treating cerebral vasospasm. To date, most of the data for this approach are limited to small case series or case reports, making it difficult to provide definitive recommendations, which in turn leads to significant practice variation across centers treating these patients.

**Transluminal Balloon Angioplasty**

For significant symptomatic vasospasm in the proximal cerebral arteries, transluminal balloon angioplasty is an effective approach to
immediately produce dilation of the involved artery and increase distal cerebral blood flow. Transluminal balloon angioplasty has two limitations: suitability limited to vessels with a diameter of 2 mm or greater and the variability in effectiveness that is based on the operator’s expertise. This intervention also has the potential for serious complication rates of about 5%, including vessel rupture, thromboembolic complications, and delayed stenosis. The results of this intervention tend to be more durable compared with those of pharmacologic intervention. No current randomized trials confirm the clinical efficacy, although the current clinical guidelines state that angioplasty is reasonable in symptomatic patients who do not respond to medical therapies, including induced hypertension.

MANAGEMENT AND PREVENTION OF MEDICAL COMPLICATIONS

Renal Complications

Intravascular Volume

As discussed previously, hypovolemia is a common complication after aSAH, and it should be avoided because it is associated with worse clinical outcomes. Intravascular volume management should target euvoolemia, with isotonic crystalloid the preferred agent for volume replacement. Assessment of intravascular volume in patients after aSAH is essential to daily management. In many institutions, fluid management is guided by calculations of the daily fluid balance of the patient. However, several studies have determined that fluid balance may not accurately reflect intravascular volume status after aSAH. Accurate monitoring of volume status may be accomplished using minimally invasive techniques. One such method is using transpulmonary hemodynamic monitoring (PiCCO). Transpulmonary thermodilution measurements that are obtained using the PiCCO system correlate well with pulmonary artery catheter measurements.
and provide an effective tool for the fluid management of patients.\textsuperscript{175,206} The PiCCO system for monitoring has fewer cardiac complications as well as fewer episodes of symptomatic vaso-spasm (\(p<0.05\)) compared with standard therapy.\textsuperscript{207}

Although recognizing that fluid balance may not accurately reflect intravascular volume, the NCS guidelines recommend that the primary assessment of intravascular volume status be close monitoring of fluid balance and clinical assessment. These guidelines continue to state that other invasive and noninvasive modalities may be used to provide supplemental information but that they should not be used in isolation. They also recommend against the routine use of pulmonary artery catheters and dependence on central venous pressure targets. As described in an earlier section, prophylactic hypervolemia therapy is not recommended.\textsuperscript{45}

**Hyponatremia**

Hyponatremia (sodium less than 135 mEq/L) is the most common electrolyte abnormality in patients with aSAH, with a reported incidence as high as 50\%.\textsuperscript{45,208} Although it is difficult to determine the contribution of hyponatremia to poor patient outcomes, the most feared complication of hypotonic hyponatremia is worsening of cerebral edema.\textsuperscript{209} Cerebral salt wasting and syndrome of inappropriate antidiuretic hormone secretion are the two most common causes of this abnormality after aSAH.\textsuperscript{147} Both cerebral salt wasting and syndrome of inappropriate antidiuretic hormone secretion are associated with hypotonic hyponatremia, with high urinary sodium content; however, the pathogenesis of the condition is different. Cerebral salt wasting is thought to be caused by an increased secretion of natriuretic peptides, mediated by activation of the sympathetic nervous system, leading to excessive excretion of sodium in the urine. The high intratubular sodium content then creates an osmotic gradient that results in increased water elimination. Therefore, cerebral salt wasting is associated with intravascular volume contraction.\textsuperscript{208,209} The syndrome of inappropriate antidiuretic hormone secretion is caused by excessive release of antidiuretic hormone, resulting in retention of free water. Consequently,
the syndrome of inappropriate antidiuretic hormone secretion results in normal or slightly expanded intravascular volume.\textsuperscript{208,209} Although often thought to be mutually exclusive conditions, cerebral salt wasting and syndrome of inappropriate antidiuretic hormone secretion may also coexist in the same patient.\textsuperscript{209}

It is important to determine the cause of hyponatremia because the management for the different causes is vastly different. The focus of management for cerebral salt wasting is replacing the salt and water losses with the use of intravenous sodium solutions with or without mineralocorticoids. Treatment of syndrome of inappropriate antidiuretic hormone secretion is focused on treating the underlying cause or, if that is not possible, using agents that target the excessive antidiuretic hormone secretion.

Most studies in this area have evaluated preventive strategies, aiming to maintain normal serum sodium concentrations (135–145 mEq/L). Several studies have evaluated the use of mineralocorticoids, such as fludrocortisone and hydrocortisone, to prevent hyponatremia and have found them to be effective when initiated early after aSAH.\textsuperscript{210,211} The exact approach for use in treating hyponatremia should be directed toward the severity of symptoms and hyponatremia, together with the duration of hyponatremia. Acute cases (less than 48 hours) with severe symptoms should be treated with hypertonic saline (3%), for which a rate of 1 mL/kg/hour increases serum sodium by about 1 mEq/L/hour, and correction should be no more than 12 mEq/L in 24 hours to minimize the risk of overcorrection and osmotic demyelination syndrome. After acute correction, continuing sodium replacement should be no faster than 0.5 mEq/hour.\textsuperscript{212} In euvoletic or hypervolemic conditions, vasopressin-receptor antagonists such as conivaptan and tolvaptan are effective in the treatment of hyponatremia. Use of these agents in patients with aSAH may lead to hypovolemia with an increased risk of worse outcomes; hence, careful monitoring has to be enacted if used in this population.\textsuperscript{209,213,214}

The NCS guidelines state that current practice varies, with free water restriction, hypertonic saline, and fludrocortisone administration being the most common methods used to manage hyponatremia in the
aSAH population. Although acknowledging the weak and low quality of evidence currently available, the NCS guidelines recommend that fluid restriction not be used to treat hyponatremia because of the potential increased risk of cerebral ischemia with hypovolemia. Both the NCS guidelines and the AHA/ASA guidelines state that early treatment with hydrocortisone or fludrocortisone may be used to limit natriuresis and hyponatremia. In addition, they both recommend limiting free water intake. The NCS guidelines further state that mild hypertonic solutions can be used to correct hyponatremia and that extreme caution to avoid hypovolemia is needed if vasopressin-receptor antagonists are administered.  

**Endocrine: Glucose Management**

Depending on the definition, hyperglycemia can occur in 30%–100% of patients with aSAH. Several studies have shown associations between admission hyperglycemia or sustained hyperglycemia and worse outcomes. Although there are currently no studies that have randomized patients with aSAH to either liberal or tight glucose management, several observational studies exist that have described patients with aSAH who were managed clinically according to various target glucose regimens. Risks found associated with hyperglycemia include increased infection and occurrence of vasospasm, whereas targeting tight glucose control (80–110 mg/dL) increased the risk of hypoglycemic events. However, limited evidence exists showing a specific target serum glucose range after aSAH. The NCS guidelines recommend avoiding hypoglycemia (serum glucose less than 80 mg/dL) while maintaining serum glucose below 200 mg/dL.

**Hematologic**

**Venous Thromboembolism**

Aneurysmal SAH is thought to induce a prothrombotic state, potentially
leading to the development of deep venous thrombosis (DVT) and/or pulmonary embolism. The incidence of DVT has ranged from 1.5% to 18%, whereas the incidence of symptomatic pulmonary embolism has been reported to be 3%. The wide range reported for DVT is a result of how DVT screening was done, with the higher incidence shown using venous ultrasonography screening. Nonpharmacologic prophylaxis using sequential compression devices is recommended on admission. The risk associated with the use of pharmacologic prophylaxis is hemorrhagic complications; however, literature is lacking to direct the optimal timing for initiating venous thromboembolism prophylaxis as well as the best pharmacologic agent. The current recommendation to withhold pharmacologic DVT prophylaxis until 24 hours after undergoing surgery or an intracranial procedure is extrapolated from the literature evaluating patients with traumatic brain injury and the general neurosurgical population. No distinction has been made between the use of unfractionated heparin and low-molecular-weight heparin as the agent of choice for venous thromboembolism prophylaxis.

Anemia

Anemia after aSAH is common, with more than 80% of patients reportedly having hemoglobin concentrations less than 11 g/dL. Anemia typically develops 3–4 days after hemorrhage with an average hemoglobin concentration drop of 3 g/dL. Factors contributing to anemia after aSAH include an aSAH-related reduction in red blood cell mass, combined with blood losses because of phlebotomy and invasive procedures, as well as hemodilution from fluid administration. A primary concern in patients who develop anemia after aSAH is that anemia may exacerbate the reduction in oxygen delivery that underlies DCI. Several observational trials have linked anemia or a larger hemoglobin reduction in aSAH with unfavorable outcomes, such as infarction, dependency, and mortality. The optimal hemoglobin threshold for patients with aSAH remains unclear. Limited evidence is currently available suggesting that hemoglobin less than 10 g/dL is associated with brain hypoxia and cerebral tissue injury,
although one study showed that a hemoglobin greater than 11 g/dL was associated with less cerebral infarction and improved outcomes after aSAH.\textsuperscript{152,233,234}

It also remains unknown whether red blood cell transfusion is the appropriate management strategy to increase the hemoglobin concentration. Red blood cell transfusion is associated with medical complications such as immunosuppression and infections in both general critical care patients and patients with aSAH.\textsuperscript{228,235} Although higher hemoglobin targets may be desirable in patients with aSAH, risks associated with red blood cell transfusion need to be considered. The AHA/ASA guidelines state that the use of red blood cell transfusion may be reasonable in patients with aSAH who are at risk of cerebral ischemia, although they state that the optimal hemoglobin goals are still to be determined. Similarly, the NCS guidelines state that patients should receive red blood cell transfusions to maintain hemoglobin concentrations above 8–10 mg/dL and that higher hemoglobin concentrations may be appropriate for patients at risk of DCI, but the use of transfusion is unknown.\textsuperscript{44,45}

**Cardiac and Pulmonary**

Observational studies have reported a high frequency of myocardial injury after aSAH, which is likely related to sympathetic stimulation and catecholamine discharge. The incidence of elevations of troponin I values, arrhythmias, and wall motion abnormalities on echocardiography is about 35%, 35%, and 25%, respectively.\textsuperscript{17,236-238} Neurogenic stunned myocardium, thought to be the most severe form of cardiac injury after aSAH, manifests as chest pain, dyspnea, hypoxemia, and cardiogenic shock with pulmonary edema and elevated cardiac markers within hours after aSAH. A wide spectrum of severity exists, including sudden death reported in about 12% of patients. Normal myocardial function commonly returns after 1–3 days; however, evidence of regional wall motion abnormalities has been shown to persist through day 9 after aSAH.\textsuperscript{208}

The most important risk factors for cardiac abnormalities appear to
be poor clinical grade and DCI. Patients who have cardiac complications are more likely to have a poor outcome because left ventricular dysfunction and low cardiac output are independent risk factors for symptomatic vasospasm.\textsuperscript{239,240} Minor cardiac enzyme elevations commonly occur after aSAH, but their significance remains unknown.\textsuperscript{45,208} Monitoring of cardiac function may be beneficial in the setting of hemodynamic dysfunction, but it is unclear whether this improves outcomes. The NCS guidelines recommend using best medical practices in the management of cardiac complications.\textsuperscript{45}

Symptomatic pulmonary complications such as pulmonary edema, acute lung injury, or acute respiratory distress syndrome are reported to occur in more than 20\% of patients with aSAH, with evidence of impaired oxygenation occurring in up to 80\% of patients.\textsuperscript{241-243} Similar to cardiac complications, the mechanism of pulmonary dysfunction is believed to be related to sympathetic hyperactivity. For the management of pulmonary complications, the NCS guidelines again state to follow the general principles of pulmonary management, including avoiding excessive fluid intake and using diuretics to target euvoolemia.\textsuperscript{45}

**Temperature Modulation**

Fever (body temperature of 38.3°C or greater) is a common complication in patients with aSAH (41\%–72\%) and is associated with worse outcome and increased length of stay, with detrimental effects independent of vasospasm.\textsuperscript{244} In addition, in a study using microdialysis measurements, fever induced cerebral metabolic distress, which was reduced with fever control.\textsuperscript{245} Although infection as the cause of fever should always be considered, noninfectious fever is common in patients with aSAH, typically starting within the first 3 days after injury. The strongest predictors of fever are a poor Hunt and Hess grade and the presence of intraventricular blood.\textsuperscript{246,247}

Several different pharmacologic and nonpharmacologic methods have been evaluated to treat fever. Antipyretics are traditionally used first line to control fever. However, agents such as acetaminophen and
ibuprofen are not effective in most patients with aSAH, perhaps because of the impaired thermo-regulatory mechanisms seen in brain-damaged patients.\textsuperscript{244,248,249} Using continuous infusions of NSAIDs may be more effective in normalizing temperature in patients with aSAH.\textsuperscript{250} External nonpharmacologic cooling methods, such as the use of fanning, evaporative cooling, cool cloths, sponging, ice packs, and cooling, are largely ineffective in aSAH. Hydrogel-coated water-circulating energy transfer pads applied externally have efficacy in reducing the fever burden. However, the time to induction of normothermia is usually slow, and problematic shivering may occur.\textsuperscript{244,251,252} A new approach to temperature control uses intravascular systems, which are more effective than external cooling devices.\textsuperscript{253,254} An important consideration when treating fever is the potential for shivering. Shivering has been reported to occur in up to 40\% of patients undergoing therapeutic normothermia with nonpharmacologic strategies. The metabolic consequences of shivering include an increase in resting energy expenditure, carbon dioxide production, and systemic oxygen consumption and a decrease in brain tissue oxygen tension. Interventions such as surface counter-warming and pharmacologic agents such as buspirone, meperidine, propofol, and other sedatives reduce shivering, but the relative efficacy of these strategies remains unknown.\textsuperscript{208,244}

**Infectious Disease**

Nosocomial infections are common in critically ill patients, with serious implications on functional outcome, mortality, and cost of care. In general, neurological and neurosurgical patients may be at an increased risk of nosocomial infections because of the increased incidence of abnormal mental status, coma, aspiration, and concomitant trauma.\textsuperscript{255} The overall frequency of nosocomial infections in neuro-ICUs ranges from 14 to 36 per 100 patients.\textsuperscript{256,257} In a study looking specifically at patients with aSAH, the most prevalent nosocomial infections were pneumonia (20\%), urinary tract infection (13\%), bloodstream infection (8\%), and meningitis/ventriculitis (5\%).
Pneumonia and bloodstream infection independently predicted death or disability at 3 months, whereas prolonged length of stay was significantly associated with all infection types. Hunt and Hess scores of 3 or greater, DCI, ICU length of stay, and intubation/mechanical ventilation were all risk factors associated with many infection types. As stated previously, it is important to rule out infection as the cause of fever in febrile patients. Other infection control measures, such as hand hygiene, elevation of head of bed to prevent aspiration, ventilator weaning trials, management of blood glucose, and early extubation when possible have been adopted in many institutions to prevent nosocomial infections.

Pain and Sedation

Headache is the most common complaint of patients after aSAH. Untreated pain can increase sympathetic activity, leading to systemic hypertension, increased cerebral blood flow, oxygen consumption, and elevated ICP. Because of the variety of complications that can occur, adequate assessment and management of headache is important in patients with aSAH. A recent retrospective study evaluated the nature, severity, and treatment of headache caused by aSAH. The study showed that headache pain after aSAH is significant and can persist through 7 days after ictus. Patients who developed cerebral vasospasm early after aSAH had a significantly higher pain score than did patients without vasospasm. Furthermore, patients who reported a pain score of 8/10 or higher usually developed vasospasm earlier than patients who reported a pain score less than 4/10.

In patients with aSAH, treatment strategies should be aimed at providing adequate analgesia without confounding the neurologic examination or contributing to morbidity. Monitoring of pain management in critically ill patients is often difficult because of patients’ inability to provide a subjective assessment of their pain level. Pain assessment tools such as the Behavioral Pain Scale and the Critical-Care Pain Observation Tool have been validated in ICU patients. These scales use indicators such as facial expression, body
movements, and compliance with the ventilator to provide a pain score. In patients who are awake and interactive, pain scales such as the numerical rating scale and/or the visual analog scale can be used.\textsuperscript{261,262}

Patients with cognitive dysfunction are also prone to increased fear, restlessness, and agitation from the inability to understand their predicament, thus requiring sedation agents. The Society of Critical Care Medicine has recommended a bundled approach to pain/sedation, promoting a pain-first approach (analagosedation).\textsuperscript{260} If a patient’s pain is adequately managed and sedation is still required, several agents are often used (see Chapter 6). Short-acting agents are typically preferred in the neurocritically ill population because of the frequency of neurological examinations.

No recommendations are currently available regarding the optimal pain/sedation assessment and management strategy in patients with aSAH. Ultimately, an individualized approach should be used, with specific aspects of drug selection requiring consideration, such as drug-drug interactions, drug-disease interactions, and cost-effectiveness.\textsuperscript{261} For more information on pain and sedation in critically ill patients, please see the Society of Critical Care Medicine clinical practice guidelines for the management of pain, agitation, and delirium in adult patients in the ICU.\textsuperscript{260}

\textbf{Paroxysmal Sympathetic Hyperactivity}

Acute aSAH can be accompanied by an excess of sympathoadrenal activity that can be termed paroxysmal sympathetic hyperactivity, CNS storming, autonomic storming, and dysautonomic hyperactivity. Clinically, this is characterized as sudden onset with hypertension, sinus tachycardia, hyperventilation, facial flushing, hyperemia, diaphoresis, hypertonia, hyperreflexia, and fever.\textsuperscript{263} Although this may occur in any patient with an acute brain injury, patients with aSAH who develop this may have prolonged ICU and hospital lengths of stay, increased medical complications, and poor long-term functional outcomes. Several pharmacologic agents have been used to treat paroxysmal
sympathetic hyperactivity, including benzodiazepines, bromocriptine, opioids, β-blockers, baclofen, α₂-agonists, and antiepileptic drugs.  

SUMMARY AND KEY LEARNING POINTS

Aneurysmal subarachnoid hemorrhage is a devastating disease and is associated with poor outcome and high mortality in a large proportion of patients. The management of patients with aSAH demands expertise to anticipate, recognize, and treat many of the neurological and systemic complications that may occur. Despite the progress made throughout the past decades, there is still a paucity of high-quality evidence to guide the management of these patients. Treatment is focused on three main areas: supportive measures, prevention of complications, and treatment of complications as they arise.

- Many mechanisms are involved in the pathogenesis of the delayed insult after aSAH.
- Managing patients with aSAH is challenging, requires a multidisciplinary team approach, and is best done at high-volume centers.
- Rebleeding is associated with a worse outcome and an increased risk of death; therefore, emergency treatment of a ruptured aneurysm is warranted.
- Medical therapies, including aggressive blood pressure control and the consideration of antifibrinolytic therapy, are recommended until the ruptured aneurysm is treated.
- The use of antiepileptic drugs for seizure prophylaxis remains controversial; it appears reasonable to limit the use of phenytoin in this role; a duration beyond 7 days for seizure prophylaxis does not seem warranted unless risk factors exist for a delayed seizure disorder.
- Nimodipine is the only pharmacologic agent that has shown beneficial effects on patient outcomes; it should be routinely used for all patients with aSAH.
Hypertension is the best component of triple-H therapy for improving cerebral perfusion and oxygenation, with clinical practice guidelines recommending a euvolemic-induced hypertension approach to managing clinical vasospasm.

DCI can be treated with combinations of blood pressure or cardiac output augmentation, angioplasty of proximal vasospastic vessels, and local administration of vasodilators.

Hypovolemia is a common complication after aSAH, and intravascular volume status should be closely monitored.

Hyponatremia is the most common electrolyte abnormality after aSAH and can be caused by cerebral salt wasting or syndrome of inappropriate antidiuretic hormone secretion; it is important to differentiate the cause because this can dictate management.

It is recommended to avoid hypoglycemia (serum glucose less than 80 mg/dL) while maintaining serum glucose below 200 mg/dL.

Venous thromboembolism prophylaxis is recommended using both nonpharmacologic and pharmacologic agents; the optimal time of initiation, agent, and dose remains unknown.

More than 80% of patients with aSAH have hemoglobin concentrations less than 11 g/dL; although higher hemoglobin concentration goals in patients with aSAH compared with general critically ill patients may be beneficial, the adverse effects associated with red blood cell transfusions need to be considered.

It is recommended to follow current best medical practices in managing cardiac and pulmonary complications.

Fever is a common occurrence after aSAH; although fever can result from a noninfectious origin, infection as the cause should always be considered; nonpharmacologic mechanisms such as hydrogel-coated water-circulating energy transfer pads and intravascular cooling devices are effective in
temperature control.

- The most prevalent nosocomial infections in patients with aSAH are pneumonia, urinary tract infections, bloodstream infections, and meningitis/ventriculitis; it is recommended that infection control measures be instituted.

- Headache is the most common complaint of patients after aSAH; treatment strategies should be aimed at providing adequate analgesia without confounding the neurologic examination or contributing to other morbidity.

LEARNING OBJECTIVES

1. Understand the risks involved with the occurrence and management of a venous thrombotic (VTE) event.

2. Describe common risk factors for a VTE present in the critically ill patient.

3. Describe the various approaches to VTE prophylaxis in the intensive care unit.

4. Implement an anticoagulation regimen in the setting of a new VTE event.

5. Discuss approaches to monitor a patient receiving prophylaxis or treatment of a VTE.

6. Describe the reversal of an antithrombotic agent.

ABBREVIATIONS IN THIS CHAPTER

ACS  Acute coronary syndromes
INTRODUCTION

Although not a common reason for being in the intensive care unit (ICU), thromboembolism (TE) either in the cardiac chamber or on the venous and arterial vessels, together with the challenges in providing the necessary management, can affect outcomes. The occurrence of venous thromboembolism (VTE) can be high and potentially devastating in the ICU, with risks of developing it related to the presence of comorbid conditions including venous stasis, hypercoagulable conditions, and endothelial damage, which are the main components of Virchow triad. The number of risk factors present, together with the magnitude of their expression, can determine the related risk and incidence of VTE. The incidence of deep venous thrombus (DVT) has
been reported as high as 28%–32% in the medical ICU population and up to 60%–70% with trauma or ischemic stroke.\(^2\) For DVT, the most common locations include the lower extremity, but it can also occur in the upper extremity, especially in regions where venous access lines or catheters existed.\(^3\) Although most TEs may be asymptomatic and undetected, symptomatic VTE including pulmonary embolism (PE) can potentially be devastating. Consequences include chronic thromboembolic pulmonary hypertension, post-thrombotic syndrome, and venous stasis ulcers. Massive PE can lead to pulseless electrical activity–related cardiac arrest and sudden death.

Management of anticoagulation carries an increased risk of bleeding complications. As such, in the presence of anticoagulation, procedures may be avoided or done differently, blood product transfusions or corrective procedures for bleeding may occur, and duration of ICU stay may be prolonged, creating additional risks for the patient. Because of this, acutely ill patients, including those in the ICU, may receive mechanical or pharmacologic VTE prophylaxis as a preventive measure. Guidelines have been developed to address the prevention or treatment of various forms of VTE, but these may be limited in the critical care setting because of bleeding, invasive procedures, loss of sites to administer injections, or just being overlooked. Given the notable challenges because of the countless variables and heterogeneity that exist and exclusion factors in clinical trials, well-controlled studies in the ICU setting are limited. Many of our current management approaches for VTE in the ICU continue to be based on clinical experiences or on limited, smaller studies. Suggestions regarding anticoagulant agent selection and the dosing regimen may not have considered challenges that may exist in the critically ill patient such as planned invasive procedures, extent of endothelial damage, transient imbalance between drivers for thrombosis and hemostasis, excessive fluid, impact of vasoactive agents on subcutaneous delivery, multisystem organ failure, low platelet counts, liver disease–related coagulopathy, or presence of mechanical circulatory devices, to just name a few. Because of the devastating consequences of VTE and related anticoagulation management, various agencies have developed
and implemented regulations or outcomes measures to encourage best practices. Examples include protocols on the initiation and maintenance of anticoagulation therapy, education, and follow-up monitoring (www.jointcommission.org/standards_information/npsgs.aspx).

**PREVENTION OF VTE**

Current guidelines have explored various forms of VTE prevention in the ICU setting. Key concepts include avoiding delays in implementing prophylaxis, understanding limitations with the use of pharmacologic agents when the risk of bleeding is high, providing agent selection dose, and understanding potential need for modifications in selected ICU populations (e.g., renal insufficiency).\(^4\) The ICU patient may be unable to ambulate or may have to be kept in a position that promotes venous stasis. If ambulation is at all possible, it should be encouraged. As mentioned, several risk factors for VTE can occur in the ICU, with some being transient and others long term. The presence of endothelial damage from invasive procedures, including use of catheters or related trauma of the venous vascular bed, also increases VTE risks. Other causes of venous stasis include heart failure, sepsis (which can be a multiple trigger), and the result of major surgery. Hypercoagulable conditions occurring in the ICU, although too many to explore in detail, should always be considered. Some may be hereditary and may not lead to a VTE event until combined with additional risk factors. Long-term risk factors can include cancer, obesity, long-term effects of trauma, or history of VTE. Transient hypercoagulable conditions may be the result of exposure to drivers for thrombosis. Examples include surgery, immobility, the use of concentrated clotting factors, immune-mediated heparin-induced thrombocytopenia (HIT), impairment of natural factors protecting against thrombosis such as loss of antithrombin (AT), acute blood loss, excessive hemoglobin from erythropoiesis-stimulating agents, cardiopulmonary failure, use of vasopressors, presence of mechanical devices within the cardiovascular system (e.g., extracorporeal life support), pregnancy, drugs such as steroids, and oral contraceptives.
Management decisions should balance the risk of VTE and bleeding when implementing or holding anticoagulation therapy and may occur on a moment-by-moment basis in more unstable situations. This may especially be true when invasive procedures are necessary or when other drivers for bleeding must be balanced with the concurrent risks of thrombosis. Common risks of bleeding include a history of bleeding complications (e.g., gastrointestinal bleeding); consequences of invasive procedures including neuraxial anesthesia; trauma; deficiency in the hemostatic process, such as loss of clotting factors; continued presence of an anticoagulant or antiplatelet agent; kidney or liver failure; and the inability to transfuse, if necessary. Bleeding at any surgical site is a concern, especially if it is closed and an accumulation of blood increases the risk of complications. The presence of a drain and the ability to transfuse may at times ease this concern. The potential volume of blood and the regions in which it occurs may also factor in. Small amounts of blood in critical surgical sites such as the central nervous system (CNS), selected ocular regions, or cardiac regions may be of especial concern. Because the risk of VTE can be high after surgical procedures, prophylaxis is encouraged as soon as possible unless bleeding-related risks exceed the risk of a VTE. In the United States, guidelines and benchmarkers encourage the initiation of prophylaxis within 24 hours of the procedure. Clinicians should be aware of and avoid any barriers for initiating prophylaxis. One example is standard dosing times and the ordering of prophylaxis postoperatively to avoid the initial dose being administered more than 24 hours after surgery. Order sets during admission and transfer in or out of the ICU should include assessment for VTE and initiation of any necessary management approaches to avoid being missed. Informatic systems should be developed to assist clinical staff in optimizing the recognition, prevention, and treatment of a VTE.

Risk assessment tools for bleeding and thrombosis have been explored but have not been validated in the ICU population. Because of the many factors mentioned, such tools may need to be combined with an individual assessment of the patient’s risk of bleeding or thrombosis. This can be especially challenging in the postprocedure period when
the risk of both bleeding and thrombosis may be high. Although VTE may not be on the problem list, all patients in the ICU should be evaluated for VTE and implementation of prophylaxis unless it is contraindicated or unless the patient is sufficiently mobile and at very low risk. Mechanical prophylaxis, although common and unrelated to the risks with pharmacologic prophylaxis, may be the only approach present in high bleeding risk situations. Support stockings may include TED support hose, which is a stocking without a compression gradient, and graduated compression stockings that provide a gradual decline in pressure from the distal to the proximal end. Intermittent pneumatic compression devices involve pressurized air into segmental diaphragms that are secured around the leg for a fixed period, which are then relaxed. These devices reduce the incidence of DVT compared with graduated compression stockings in high-risk patients with or without pharmacologic prophylaxis. This provides a wavelike effect to move flow through the veins and prevent the pooling of blood. When pharmacologic prophylaxis is not an option, it is important to assess whether mechanical approaches have been considered or whether they are present and are actually being done. Stockings can be uncomfortable, and at times, they are found in the room but not on the patient. As such, the use of stockings on the patients should be assessed each day. Weight loss or changes in swelling may alter the effectiveness of the stockings, and cornstarch or talcum may be applied at times to assist patients with moist skin in pulling them up. For effective DVT prophylaxis, compression gradients of 20–40 mm Hg may be targeted. If the compression devices are only in the foot region, compression pressures on the higher end may be considered.

In some situations, an inferior vena cava (IVC) filter (which may be temporary or permanent) may be placed. However, thrombus formation within the filter creates challenges in removal and, in some cases, can lead to a need for systemic anticoagulation. In rare cases, the device could migrate, so for a combative patient, use of restraints should not run over the abdominal region, where any abrupt motion and resulting pressure in the region of the filter can dislodge the IVC. In general, the use of IVC filters has been discouraged unless the risk of VTE is high.
and other means of prophylaxis are not feasible. In addition, continuous assessment to determine when pharmacologic prophylaxis can be added should be a component of the ICU stay. Routine use of ultrasonography to detect VTE should be avoided, in general, because it is unclear whether this changes the incidence of symptomatic events, and a positive finding could be noted as an event irrespective of being treated. The various pharmacologic agents used for VTE treatment and prophylaxis are listed in Table 23.1. Considerations and doses for these agents in VTE prophylaxis are listed in Table 23.2.

TREATMENT OF VTE

The occurrence of a DVT, either preexisting and still under anticoagulation therapy or occurring during admission, creates a more compelling situation. In acute VTE, higher levels of anticoagulation may initially be considered, creating a higher risk of bleeding. Decisions to treat or continue treatment may depend on the location and timing of the VTE. In general, VTEs occurring above the knee may be treated for at least 3 months for a first occurrence, and potentially for life if sustained risk factors are present or recurrent. Venous thromboembolism may also be defined as provoked, meaning that it occurred in relation to a specific event (e.g., elective knee surgery) and carries a lower concern for extended therapy. Non-provoked VTE occurs when the VTE was not related to an identified high-risk situation, occurring more spontaneously. It may be a more difficult decision to hold anticoagulation therapy with non-provoked VTE, especially in the ICU setting when risk factors for thrombosis are present.

Half-life listed was determined in normal healthy individuals, and not in the critically ill for which it can be considerably longer.

AT = antithrombin; UFH = unfractionated heparin; Hr = hours; Conc = plasma concentration; wk = week; min = minutes.

Initial therapy for an acute VTE may depend on the location of the thrombosis, its size, and any additional symptoms. Pulmonary embolisms may be classified as massive when congestion in the pulmonary circulation leads to expanded volume in the right ventricle upstream where the cardiac wall presses against the left ventricle, reducing stroke volume and leading to hemodynamic insufficiency. In this situation, initial therapy may include thrombolytic agents followed by a heparin infusion and eventually a long-term oral anticoagulant. For a sub-massive PE, the decision to use thrombolytic therapy may be weighed against the risks involved and the potential benefits. Most of the symptomatic PEs in the ICU are initially treated with a parenteral anticoagulant, followed by a long-term anticoagulant for at least 3 months, if possible (Table 23.3).

*a Orthopedic hip/knee prophylaxis.

CrCl = creatinine clearance; CRRT = continuous renal replacement; IHD = intermittent hemodialysis; INR = international normalized ratio; IV = intravenous(ly); kg = kilogram; PO = oral(ly); q = every; SC = subcutaneous(ly); SLEDD = slow duration dialysis; VTE = venous thromboembolism.

Often, patients admitted to the ICU with pulmonary symptoms may have PE included in the potential problem list. The diagnosis of the PE may be assessed by a chest computed tomography (CT) or a ventilation/perfusion scan. Because the consequences of a VTE, and especially a PE, can include sudden death or long-term pulmonary insufficiency (pulmonary hypertension), therapy should not be delayed
for the results of diagnostic test results, but instead, instituted promptly and continued until a VTE or PE is ruled in or out. Additional approaches to therapy can include surgical removal or catheter-directed thrombolysis (Table 23.4).

In the ICU, parenteral anticoagulation for at least 5 days is desired, and include transitioning (bridging) to long-term anticoagulation; typically, warfarin is used if there is no need to discontinue anticoagulation. This in part may be attributed to its ability to be rapidly reverse heparin and warfarin if necessary. Anticoagulation plans using longer-acting agents should address any planned procedures with risks of bleeding and be held until resolved. When transitioning to warfarin, the parenteral agent should be continued until the international normalized ratio (INR) is above 2. Guidelines suggest that INR greater than 2 plus 1 additional day; however, specific benefits of this particular timing has not been tested in clinical trials. Newer options include the direct-acting oral anticoagulants; however, most of these have been explored outside the critical care setting. Several limitations may exist, including the potential need to adjust dosing in organ failure, ability to measure the degree of effect or loss of effect for invasive procedures, and ability to reverse their effects. It is unclear whether they may be beneficial for other indications such as mechanical devices or in concurrent acute coronary syndromes (ACS) when other, more established agents have been used. Other options include 3 weeks of rivaroxaban 15 mg orally twice daily, followed by a dose deescalation to 20 mg daily, or apixaban 10 mg orally twice weekly for 7 days, followed by 5 mg twice daily. Dabigatran and edoxaban have been explored in VTE treatment but initiated after an initial period of parenteral anticoagulant therapy. With the use of the newer agents, there is no need to overlap with another anticoagulant. If the ICU stay is short and the patient can be discharged home, transitioning to long-term oral anticoagulation can be completed on an outpatient basis if the therapy can safely be implemented and the follow-up management arranged.

Other modalities for VTE management may include invasive procedures such as thrombolysis by intravenous infusion, which is
considered for a massive PE and hemodynamic instability as the result of congestion in the right ventricle compressing against the left ventricle and reducing cardiac output. This strategy may also be considered in selected submassive PEs as well on a case-by-case basis. Catheter-directed thrombolysis incorporating thrombolytic therapy (e.g., EKOS catheters) or surgical thrombectomy can be used to remove the clot. For very high bleeding concerns outweighing those of the thrombosis when anticoagulation therapy is held, or if a lower intensity of anticoagulation is necessary, monitoring of a DVT can include repeat ultrasonography to determine whether the thrombosis is extending.

ANTICOAGULATION AGENTS

Unfractionated Heparin

Unfractionated heparin (UFH) is administered parenterally either by bolus or continuous intravenous infusion or subcutaneously for many indications in the critically ill patient. Heparin administered intravenously is completely bioavailable, but it is reduced to about 30% when administered subcutaneously, depending on the site of injection or the presence of vasopressors, which can decrease absorption. Heparin can be used to coat catheters to prevent thrombosis on their surface as well as prophylactically to prevent VTE, or it can be used in the acute management of VTE as well as several other situations. The advantage of heparin is its rapid onset of effect, its rapid removal out of the system, and the ability to reverse its effects rapidly with protamine. Heparin is available in many concentrations, and it is important to use standard concentrations for the various uses to minimize potential errors. For the treatment of VTE, premixed solutions of heparin are available, and it is best to choose one standard concentration and incorporate that into VTE management guidelines, order sets, and products that are dispensed from the pharmacy. Because heparin is removed by the liver, the dose need not be adjusted for renal insufficiency. It can be reconstituted in either dextrose or saline, providing options in selected situations when
another option may be preferred.

For VTE prophylaxis, UFH may be administered subcutaneously or by continuous intravenous infusion. In the International Medical Prevention Registry on Venous Thromboembolism (IMPROVE), a multicenter registry involving 15,156 acutely ill hospitalized medical patients of whom 5% were in the ICU, a marked variation in practices was seen in dosing frequency of low-dose UFH used to prevent VTE. Combined with other comparisons and the low quality of evidence, including the lack of head-to-head comparative trials exploring twice-versus three-times-daily dosing, no compelling evidence exists to support a benefit of three-times-daily low-dose UFH compared with twice-daily dosing for reduction in VTE or increase in bleeding. What is unclear is identifying the optimal approach in special populations that were not the focus of clinical trials such as surgical versus medical critically ill populations, populations with obesity, or populations with the presence of a hypercoagulable or bleeding state. This is evidenced by the fact that 7.7% of 3,746 medical-surgical ICU patients developed a DVT despite adequate thromboprophylaxis with either low-dose UFH or low-molecular-weight heparin (LMWH). A multivariate regression analysis suggests that patients with a personal or family history of TE, those with an elevated body mass index (BMI), and those receiving vasopressors appear more likely to have had failed standard thromboprophylaxis strategies. Although patients may prefer fewer daily injections, the lower dose can be presumed to lower the level of anticoagulation and increase the risk of thrombosis, but as mentioned previously, this has not been shown in clinical trials. Empirically, patients at an advanced age (e.g., older than 80 years) with a low body weight (e.g., less than 50 kg) may have a more pronounced effect from heparin. In such cases, 5,000 units twice daily may be considered, or a trough activated partial thromboplastin time (aPTT) can be measured to assess whether a higher-than-desired anticoagulation effect is present. Although there is no supporting evidence on using continuous infusions for prophylaxis, it is another consideration when target goals are a small 10-second rise in aPTT over baseline or when measuring an anti-factor Xa (anti-Xa) activity concentration of 0.2–0.3 unit/mL.
When using heparin for prophylaxis in the absence of an acute clot, a bolus dose may be unnecessary.

**Table 23.3** Considerations with Anticoagulants for Treatment of VTE\(^{a,b,9,11-13,21}\)**
**Dosing in hemodialysis** describes the approach the dose that was explored and may not apply to other forms of dialysis.

Values for the aPTT depend on the reagent lot and range that fits within the 0.3–0.7 anti-Xa unit samples (typically, 30 heparin patient samples are used for the calibration). In the treatment of acute VTE, values in the upper range (e.g., 0.5–0.7 anti-Xa units) may be

\(^a\) Dosing in hemodialysis describes the approach the dose that was explored and may not apply to other forms of dialysis.

\(^b\) Values for the aPTT depend on the reagent lot and range that fits within the 0.3–0.7 anti-Xa unit samples (typically, 30 heparin patient samples are used for the calibration). In the treatment of acute VTE, values in the upper range (e.g., 0.5–0.7 anti-Xa units) may be
In the treatment of acute VTE, heparin is commonly used in the ICU and initiated as an intravenous bolus followed by a continuous infusion, with a desire to achieve and sustain target goals as soon as possible. The approach to dosing may depend on additional factors such as the concurrent use of a thrombolytic agent or concurrent bleeding issues. For example, a patient with an acute major bleeding episode who subsequently develops a VTE may be dosed on the basis of a risk assessment of the VTE (including location and severity) versus the risk of additional bleeding. The initial bolus may vary, if done at all, and may empirically be based on a set number of units (e.g., 2,500–5,000 units) or loading doses individualized using the patient’s weight (e.g., 80 units/kg initially and potentially a lower amount when subsequent aPTT or anti-Xa activity concentrations are below target). If the bleeding concerns are very high, a lower bolus, if any at all, and a lower infusion rate may be considered.

Currently, no standard proven approach to the optimal infusion rate of target therapy goals has been established. A variety of approaches to continuous dosing exist, with dosing at 18 units/kg/hour being the most commonly used starting rate for an acute VTE. The aPTT or anti-Xa activity can be measured 4–8 hours after initiating the infusion and the dose subsequently adjusted. The duration of effect by the bolus on the measured activity may be longer with higher doses. If no bolus is used, activity assessment can be done at 4 hours. A delay of 6–8 hours may be required, however, if a bolus is given to avoid elevated values driven in part by the bolus and resulting in infusion rates that may be below target. Monitoring patients on anticoagulation with a VTE includes assessing the VTE and, if it is continuing to expand, the bleeding or potential complications such as HIT. Typically, a complete blood cell count and aPTT or anti-Xa activity is checked before initiating the infusion and then periodically as needed to assess the impact of the therapy.

Hct = hematocrit; Hgb = hemoglobin; hr = hours; IV = intravenous; kg = kilogram; LMWH = low-molecular-weight heparin; mg = milligram; PE = pulmonary embolism.

In rare cases, such as in the loss of intravenous access or if long-term heparin is needed, a subcutaneous route may be considered. To determine a subcutaneous dose from a currently administered intravenous infusion, the following equation may be used:

\[
dose_{SC\text{ administered every 12 hours}} = (\text{last IV infusion rate/hr} \times 24) \times (1.2)/2
\]

where IV is intravenous, SC is subcutaneously, and “1.2” reflects the 20% or so loss of bioavailability with the sub-cutaneous route.

The common 250 unit/kg every 12 doses for VTE treatment is based on the concept of 20% over the common 18-unit/kg/hr intravenous infusion rate used in VTE.

There are several approaches to measuring the intensity of heparin
therapy. Target ranges have in general been determined from experiences using the aPTT; however, discordance between the aPTT and the other assay approaches exist.\textsuperscript{23-28} Previously, a target aPTT prolonged to 1.5–2.5 times the patient’s normal baseline value was used.\textsuperscript{29-31} However, it was recently observed that different assay reagent sensitivities exist, leading to subtherapeutic or excessive doses of heparin. Several factors can drive the variability in reported laboratory results with either the aPTT or the anti-Xa activity value. These include the re-agent used and its sensitivity to heparin, presence of other factors influencing the result such as prolongation of the aPTT that is seen with lupus anticoagulant antibodies, certain congenital factor deficiencies, excessive factor VIII, fibrinogen or warfarin in the case of the aPTT, and AT deficiency for the anti-Xa activity assay.

The current recommendations of the American College of Chest Physicians and the College of American Pathologists indicate that patients should be treated with intravenous UFH to prolong the aPTT to a range that corresponds with a whole-blood heparin concentration of 0.3–0.7 unit/mL by the anti-Xa heparin assay or 0.2–0.4 unit/mL by protamine titration.\textsuperscript{32,33} In recent years, some institutions have shifted from measuring the aPTT to using anti-Xa activity. Institutions that have made the change have noted fewer dosing titrations and earlier achievement of target goals.\textsuperscript{34} However, hard outcomes such as any differences in the resulting heparin dose, incidence of thrombosis, or incidence of bleeding have not been determined. Given the high variability in reagents and the reported results between laboratories for both the aPTT and the anti-Xa assays, it is important to know the specifics of the assay used to adjust heparin (or LMWH) therapy.\textsuperscript{35,36}

Several challenges can occur with the management of heparin infusions. A diurnal pharmacokinetic elimination pattern has been shown with heparin infusions where higher aPTT or anti-Xa values can occur during sleeping times and then lower values during awake cycles.\textsuperscript{37} Because sleep cycles are often inconsistent in the ICU, it is difficult to coordinate them with measuring the level of anticoagulation. Another challenge is the observation of “heparin resistance,” in which the aPTT or anti-Xa concentration does not increase despite titration to higher
heparin infusion rates (e.g., above 25 units/kg/hour and values are still at baseline). Causes include elevated fibrinogen or factor VIII concentrations, which may limit the aPTT response, and depression in AT, which may blunt the action of heparin and potentially be missed if an anti-Xa assay is used that incorporates supplemented AT within the assay. To determine whether resistance is present, an AT, aPTT, anti-Xa assay, fibrinogen, and factor VIII concentration, if available, may be considered. Another means of determining potential resistance to heparin is to measure either the aPTT or the anti-Xa assay shortly after a bolus dose. If there is no response with either test, consider other approaches to anticoagulation management. Alternative tests such as activated clotting time (ACT) may be another consideration to assess whether an anticoagulation response is present. For VTE management, the low-range ACT is suggested because it may be better at detecting heparin concentrations in the target range.\textsuperscript{35}

**Low-Molecular-Weight Heparin**

Another option in patients at lower concern for bleeding and with no perceived need to immediately reverse anticoagulation includes use of an LMWH or one of the newer oral anticoagulants. This may also be a consideration when intravenous access is limited or there is inability to measure laboratory values to adjust therapy. The LMWHs are now commonly used for the prevention and treatment of VTE and may be seen in the ICU if emergency reversal is not a concern. The low-molecular-weight tinzaparin (no longer available in the United States), dalteparin, and enoxaparin have been determined to be safe and effective in the prevention and treatment of VTE; however, most of the studies with them involved patients outside the ICU.

Low-molecular-weight heparins administered subcutaneously are about 87%–92% bioavailable ($F = 0.87$–$0.92$), which is considerably greater than that with sub-cutaneous doses of UFH (30%; $F = 0.3$).\textsuperscript{38} The degree of bioavailability may be lower in the critically ill surgical or medical patient.\textsuperscript{39-41} An impaired response to standard dosing as measured by anti-Xa, possibly leading to a greater incidence of VTE,
has been seen.\textsuperscript{42,43} Site of administration may be a factor. In one analysis of enoxaparin, the measured anti-Xa activity was significantly lower in patients with obesity when administered in the thigh than when administered in the abdomen.\textsuperscript{44}

Compared with UFH, the LMWHs have a longer half-life and a more predictable anticoagulant response to weight-adjusted doses, allowing for either once- or twice-daily administration. The actual body weight should be considered for dosing, and it is suggested to avoid capping the dose at a certain weight (Table 23.2 and Table 23.3).\textsuperscript{45}

When switching from UFH to an LMWH, the LMWH can generally be given when discontinuing the UFH infusion to simplify the process. Acute thrombus or bleeding is unlikely to occur when a slight difference in the time between discontinuing the UFH and initiating the LMWH occurs. For transitioning from an LMWH to a UFH infusion, consider initiating the UFH infusion when the next LMWH dose would be administered. A bolus dose of UFH is probably unnecessary.

The management end point for anticoagulation therapy should focus on potential bleeding and thrombosis or other related undesirable events. Studies comparing various agents in general have shown no significant differences in lowering either thrombosis or bleeding.\textsuperscript{46,47} Clinicians should be cautious with measuring anti-Xa activity and applying the results to a dosing modification, especially when doses are outside those studied in clinical trials as supporting literature with hard outcomes is very limited. This would also hold true with special populations, including those with obesity and renal failure. It can be problematic to have a level drive a dosing modification in a direction that is very uncomfortable given the current clinical situation.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that mimics the 5-sugar moiety binding sequence that gives heparin the ability to activate AT. Fondaparinux is highly selective for factor Xa inhibition with no appreciable inhibition of factor IIa (thrombin). Fondaparinux rapidly binds to AT, causing an irreversible conformational change. It is
subsequently released, allowing binding to other AT molecules. The ability of fondaparinux to trigger an immune-mediated HIT response is potentially less likely given its small molecular size and the absence of the additional side chains. Although HIT cases attributed to fondaparinux have been reported, fondaparinux is now an optional alternative anticoagulant in the management of HIT, or for VTE prophylaxis when there is a history of HIT.48

Fondaparinux is available in several different strengths (2.5, 5, 7.5, and 10 mg) for once-daily subcutaneous injection. Evaluated in several phase II trials, fondaparinux is approved for VTE prophylaxis in hip and knee replacement, treatment of acute DVT and PE, and treatment of ACS. Fondaparinux dosing in the treatment of a VTE is based on weight: 5 mg (weight less than 50 kg), 7.5 mg (weight 50–99 kg), and 10 mg (100 kg or greater). However, the dose for ACS or VTE prophylaxis post-hip or knee is a fixed 2.5 mg regardless of patient weight. In one phase II dose-response trial, there were no observed differences in recurrent VTE rates or bleeding events between patients weighing 50–100 kg receiving fondaparinux 5, 7.5, or 10 mg subcutaneously daily.49 In a larger randomized phase III trial, weight-adjusted fondaparinux was as effective as continuous infusion UFH and weight-adjusted enoxaparin in the treatment of VTE, with a slight decrease in thrombotic events countered by a small increase in bleeding events.50,51 Another phase II trial of ACS evaluating doses of 2.5, 4, 8, and 12 mg showed no difference in the primary end point of myocardial infarction, recurrent ischemia, death, or bleeding. Overall, fondaparinux is effective in the prophylaxis against and treatment of VTE and may be more potent than originally perceived.

Fondaparinux is almost entirely renally eliminated and has a long half-life; thus, its use in patients with moderate to severe renal impairment is discouraged. To date, fondaparinux doses of 1.5 mg daily and 2.5 mg every other day in severe renal impairment have been described only in case reports and case series and a single cohort analysis.52,53 Fondaparinux use in hemodialysis seems to provide an adequate level of anticoagulation when properly dose adjusted. Dosing in dialysis appears to require a further dose reduction to either 0.05
mg/kg or 2.5 mg before the dialytic session. Providers should consider residual renal function because anuric patients are potentially more likely to accumulate fondaparinux at a faster rate, thus increasing the risk of a potential bleeding event compared with oliguric patients.

Much of the data regarding the use of fondaparinux for VTE prophylaxis and treatment in obesity are confined to observational studies and subgroup analyses of larger randomized controlled trials. Fondaparinux is given as a single 10-mg subcutaneous, once-daily injection for patients weighing more than 100 kg. In one subgroup analysis, fondaparinux 10 mg subcutaneously daily was evaluated in patients weighing as much as 166 kg with a BMI of 46 kg/m². Fondaparinux appeared to be as effective as therapeutic twice-daily enoxaparin and intravenous UFH in the initial treatment of VTE. Fondaparinux had numerically fewer recurrent VTE and major bleeding events than did enoxaparin and UFH. Use of fondaparinux in the obese population provides the opportunity for improved compliance compared with a twice-daily therapy, using multiple syringes, together with the convenience of a single once-daily injection.

Dosing fondaparinux for VTE prophylaxis is even less clear. The current U.S. Food and Drug Administration (FDA)-approved dose of 2.5 mg subcutaneously daily has been debated regarding whether the dose should be increased for those with morbid obesity or at a certain weight cutoff. Some authors have suggested a dose increase to 5 mg subcutaneously daily in weights greater than 120 kg because of a lack of data for the approved prophylactic dose in this population. Anti-Xa activity within range greater than half of the time in the patient with morbid obesity (BMI less than 50 kg/m²; weight less than 150 kg) with fondaparinux 2.5 mg subcutaneously daily has also been seen.

Reversing Heparin and LMWH Effect

The effects of UFH and, to a lesser degree, LMWH can be neutralized using protamine sulfate. In general, each milligram of protamine sulfate neutralizes around 100 units of heparin calcium, with a maximum of 50 mg as a single dose suggested. Excessive dosing of protamine
should be avoided because it can independently promote bleeding. Protamine should be administered slowly over at least 10 minutes to reduce the possibility of hypotension and anaphylaxis.

When dosing protamine, the clinician should consider how long heparin has been held. Because UFH administered intravenously has an elimination half-life of 60–90 minutes, only heparin given during the preceding several hours needs to be considered when calculating the dose of protamine sulfate. For example, a heparin infusion at 1,250 units/hour requires about 30 mg of protamine sulfate for neutralization. Neutralization of UFH administered by subcutaneous injection may require a prolonged infusion or repeat doses of protamine sulfate because of continued absorption from the site of administration. The effectiveness of the neutralization can be assessed by measuring either the aPTT or the anti-Xa activity. For the LMWHs, protamine only partly neutralizes their effects, with a potentially greater response to higher sulfated compounds (tinzaparin > dalteparin > enoxaparin); however, the clinical significance of this is unclear. A 1-mg dose of protamine for every 100 anti-Xa international units of dalteparin or 1 mg of enoxaparin has been recommended for reversal if less than 8 hours has elapsed since the dose of LMWH.

Fondaparinux is currently without a specific antidote. Protamine is ineffective in neutralizing the anticoagulant effect of fondaparinux because of the lack of sulfations in the synthetic pentasaccharide. Doses of recombinant activated factor II (rFVIIa) up to 90 mcg/kg have shown only partial correction in the thrombin-generating capacity of an ex vivo analysis, whereas a low dose (20 units/kg) of the activated prothrombin complex concentrate (aPCC) factor eight inhibitor bypassing activity (FEIBA) showed a complete correction in the assay.

**Direct Thrombin Inhibitors**

The parenteral direct thrombin inhibitors (DTIs), typically administered by continuous infusion, provide an alternative option when commonly used therapies such as UFH or LMWH cannot be used (Table 23.5).
This may occur in patients who have heparin allergies, concerns for HIT, or AT deficiency. The two currently available parenteral DTIs are argatroban and bivalirudin. Most of the experiences with these agents in the management of VTE arise in the setting of acute HIT-with or without associated thrombosis, HIT post-initial therapy for VTE, or history of HIT requiring VTE prophylaxis. Fondaparinux may be an option in some cases where use of a DTI infusion is not desired and a long acting agent is permissible. The elimination half-lives for argatroban and bivalirudin are relatively short, according to an analysis of healthy individuals. In the critically ill patient, especially in the presence of heart, kidney, or liver dysfunction, elimination rates can be considerably longer, thus taking longer to reach steady state and longer for the effects to leave after discontinuing the infusion. In addition, the amount of drug needed to achieve treatment targets may be lower. The infusion rate is typically adjusted on the basis of observed aPTT or dilute thrombin time values. The aPTT target concentrations are based on achieving ratios of 1.5–2.5 for bivalirudin and 1.5–3.0 for argatroban from the patient’s baseline value. The upper end of the range is commonly targeted in patients at higher thrombosis concerns such as for acute thrombosis, and the lower end for thromboprophylaxis. Although the aPTT is also used for heparin, the target value during DTI therapy may be different.

*aNo nationally standardized test; thus, test results and sensitivity may vary between institutions.

aPTT = activated partial thromboplastin time; dTT = diluted thrombin time; ECT = ecarin clotting time; HIT = heparin-induced thrombocytopenia; min = minute; TT = thrombin time; PCI = percutaneous coronary intervention.

Argatroban is primarily eliminated in the liver, but it also requires dosing reductions in renal insufficiency.\(^61,62\) The aPTT target is 1.5–3 times control according to the range set in the ARG 911 trial. Although the prescribing information notes starting at 2 mcg/kg/minute, the mean dose in the ARG 911 and the subsequent postmarketing ARG 915 trial was lower at 1.5–1.6 mcg/kg/minute. Experiences with the use of argatroban in the critically ill patient suggest even lower doses less than 1 mcg/kg/minute.\(^63\) For liver failure with a Child-Pugh score greater than 6 or a total bilirubin greater than 1.5 mg/dL, the dose should be reduced to 25% of normal, or 0.5 mcg/kg/minute; however, lower doses may occur.\(^22\) For renal insufficiency, the observations have suggested a dose reduction of 0.1–0.6 mcg/kg/minute for every 30-
mL/minute decrease in CrCl. There is no known reversal agent for argatroban, and it is not removed by hemodialysis.

Bivalirudin is another DTI primarily developed for use in ACS; however, there are several postmarket, single-center experiences describing its use in the management of HIT at much lower doses. The commonly targeted aPTT value is 1.5–2.5 times control, and it is eliminated primarily by enzymatic degradation by thrombin; however, the dose may need to be reduced as renal function declines. The common dose is 1.5 mg/kg/hour; however, lower doses are commonly seen in the critically ill patient as well. Unlike argatroban, bivalirudin may be removed by hemo-dialysis, and enzymatic elimination may be impaired in hypothermia. The aPTT should not be measured during, or for several hours after, intermittent hemodialysis. In the setting of continuous renal replacement therapy, a higher dose may be necessary to account for removal by hemofiltration. Although package labeling suggests that steady state may occur within hours, it may take considerably longer in the critically ill patient. One strategy is to assess an aPTT within a few hours of initiating the infusion, and if the value is in the upper part of the target range or above (and before reaching steady state), an excessive level of anticoagulation could shortly occur. As such, the infusion rate may tapered down earlier as a precaution. In a bleeding patient with acute thrombosis concerns, the infusion can be initiated at a lower rate and titrated to effect using more frequent aPTT assessments.

Management of bleeding during parenteral DTI therapy includes targeting lower aPTT values, giving blood transfusions as needed, and providing hemofiltration, if necessary, for bivalirudin. Concentrated clotting factors, fresh frozen plasma, and vitamin K do not expedite removal; however, in theory and according to very limited case experiences, it is possible that the thrombin burst with rFVIIa can accelerate the enzymatic removal of bivalirudin. Of additional note, heparin and the parenteral DTIs can independently cause an increase in measured INR values. These are not thought to reflect independent pharmacologic activity, but they are the result of influencing the INR assay. The higher the drug
concentration, the greater the impact on the observed INR value, which may vary between laboratories and the assay used. Some laboratories perform an additional step and neutralize the heparin before measuring the INR, eliminating the influence. It is important to know whether your laboratory does this neutralization step because many clinicians may otherwise target an INR of 2.5 or higher with warfarin before discontinuing heparin to account for the assay differences. In the absence of warfarin, an INR value at or above target ranges does not indicate a need to discontinue the infusion, but it could be an indication of excessive anticoagulation effect from the DTI, again depending on the sensitivity of the INR assay to the DTI.

For the DTIs, the INR assay is more sensitive to argatroban followed by bivalirudin. This can be an advantage in patients for whom the aPTT response is not very robust. In some patients, the aPTT response curve may flatten and may not increase despite significant increases in the infusion rate. In such situations, a thrombin time can be measured, and if a very high result is noted, excessive anticoagulation can be present despite a low aPTT. In such situations, the dose can empirically be capped and the patient monitored for thrombosis and bleeding. The effect on the aPTT could be transient, so it should continue to be measured, and if excessive values subsequently occur, the infusion rate might need to be reassessed.

ORAL AGENTS

Vitamin K Antagonists

For longer-term anticoagulation, the vitamin K antagonists have been the preferred agent for treatment of a VTE after initial management with a parenteral anticoagulant, or prevention of VTE. This class of agents, for which warfarin is the most common agent used in North America, decreases the production of the vitamin K–dependent clotting factors (II, VII, IX, and X) in the liver to lower concentrations, blunting the drive for thrombosis. The INR is the common means for measuring the intensity of anticoagulation with vitamin K antagonists, where target
values of 2–3 are typically used in the management of VTE. Many factors can influence the dose response to warfarin; these are described in detail elsewhere. Many can be present in the critically ill patient, typically leading to lower doses. Examples include renal, liver, and heart failure; concurrent drug interactions; inflammatory responses; infections, and low vitamin K stores. Some such as rifampin or continuous tube feeds, or improvement in organ function and resolution of an infection, may lead to a dosing increase.

For an acute VTE, warfarin can be initiated once anticoagulation with a parenteral agent has been established. This would be 4 hours after an LMWH dose or when a therapeutic aPTT value on UFH occurs. When initiating therapy, the clotting factor with the shortest life span, factor VII, is eliminated faster than is factor II. Because factor II remains longer and is the primary driver for thrombosis, rapidly rising INR values may underpredict the level of anticoagulation. Before initiating warfarin, a baseline INR should be determined and then measured daily, if possible, at least 8–10 hours post-dose (longer may be preferred, if feasible) to assess any early potential dose response. Because warfarin is eliminated through the liver, lower doses may be common in liver disease. However, renal failure may also block the elimination of selected cytochrome enzymes (in the case of warfarin 2C19), resulting in lower warfarin dosing. If the INR is not a feasible test because of other influencing factors (e.g., lupus anticoagulant), clotting factors such as factor II or X can be directly measured. For acute VTE, the parenteral bridge therapy may be discontinued once the INR is greater than 2 and determined to be believable. Unexpected INR values may be repeated to determine if the result is believable or not before a dosing decision.

Warfarin can be crushed, and the effects of a particular dose may not reach maximal influence for several days; however, in some patients, a marked response may be seen after 8–12 hours. Thus, an INR may be measured at some point after the first dose to determine whether the patient is very sensitive to it.

Directing Acting Oral Anticoagulants
Until recently, warfarin was the mainstay of prolonged VTE therapy; however, dosing can be difficult because of the many influencing factors. Several new agents recently became available and have been approved for VTE management. Dabigatran is a DTI, and rivaroxaban, apixaban, and edoxaban are factor Xa antagonists. Patients enrolled in the clinical trials exploring the use of these agents for VTE were probably not critically ill, limiting any clear insights of any advantages over warfarin. The designs of the VTE trials were also very different. Although most patients received heparin or an LMWH initially while being randomized, initial therapy for edoxaban and dabigatran included a parenteral agent for 1 week or so, which was then switched to oral therapy. For rivaroxaban, a higher dose of 15 mg twice daily was administered for 3 weeks, followed by a lower 20-mg once-daily dose. For apixaban, the initial dose was 10 mg orally twice daily for 7 days, followed by 5 mg twice daily in VTE treatment. Rivaroxaban and apixaban can be crushed and mixed for nasogastric administration; however, the dabigatran capsule should not be opened; rather, it should be given as manufactured because any alterations can substantially increase the bioavailability 8- to 10-fold.\textsuperscript{70-72}

Critically ill patients such as those with severe liver failure or high risk of bleeding were pre-determined exclusions in the clinical trials. Unlike warfarin, which requires invasive INR tests for adjusting dosing, the newer agents do not require or have commonly available measures of anticoagulation intensity and subsequent dosing adjustments. However, drug interactions do exist with the newer agents, and the presence of organ failure can result in higher levels of anticoagulation that may be difficult to recognize. Assays to directly measure the intensity of anticoagulation with the newer agents have been developed or are under development; however, they are not commonly available.

The thrombin time is very sensitive to the presence of dabigatran and can be used to detect its presence; however, it can exceed maximum values when normal serum concentrations are present.\textsuperscript{73} For the INR, prothrombin time, and aPTT, the various assay regents available can respond differently to the presence of the newer agents, depending on their sensitivity. Elevated values beyond what may be
expected for a selected assay may be a signal for excessive anticoagulation, especially if a clinical condition (e.g., overdose, organ failure, or a drug interaction) is present. Anti-Xa activity can be increased depending on the assay and the calibrator used, creating notable variability in results and limiting its usefulness. Several agents that can directly reverse the DOACs (direct oral anticoagulants) are currently under development. Idarucizumab is a monoclonal antibody fragment (Fab) currently in phase III trials but recently approved by the FDA specifically binds to dabigatran and rapidly neutralizes its anticoagulant effect in minutes. It has no activity against other anticoagulants. In the REVERSE-AD phase III trial, the median time for hemostasis took 11 hours. As such, it is unclear in situations with massive hemorrhage whether concurrent use of a concentrated clotting factor or tranexamic acid is necessary if rapid hemostasis is critical. Andexanet alfa is a modified recombinant version of factor Xa that works as a decoy to block any anticoagulant with anti-Xa activity. Both agents are initiated with a bolus dose; however, andexanet may require continued therapy with a continuous infusion.

During anticoagulation therapy, situations may arise in which the concerns for bleeding outweigh those for thrombosis, either for high bleeding risk situations, including necessary invasive procedures, or active bleeding. Approaches can include reducing the level of anticoagulation, holding anticoagulation, expediting removal, or independently promoting hemostasis. Agent-specific reversal strategies are listed in Table 23.6. For a bleeding event, if a patient has a history of VTE, the reversal approach may consider the brevity of the situation. If severe morbidity or mortality is perceived and no emergency reversal occurs, more aggressive management may be considered. If time permits or a desire not to fully reverse effects is present, more conservative reversal regimens can be considered and titrated to the desired effect.

In the critical bleeding situation, administration of reversal approaches should be accomplished without delay. For heparin or LMWH, protamine can be administered. For warfarin, a prothrombin complex concentrate (PCC) together with parenteral vitamin K can be
given. Three-factor PCCs (which have a lower amount of factor VII compared with factors II, IX, and X); four-factor PCCs, which have all four factors; and, to a limited extent, aPCCs, which have all four factors with factor VII in a activated form, have been explored. In addition, recombinant activated factor VIIa (rVIIa) has been explored for reversing anticoagulants. The dosing of PCCs to reverse warfarin may depend on the observed INR; however, waiting for a value to return before dosing may delay therapy. If the INR is not yet available, therapy can be initiated with the initial three or four factor PCC dose of 25 units/kg using a weight up to 100 kg, and if the INR suggests a higher dose, an additional agent can be given. To avoid delays in the admixture of several vials, therapy with a single 1,000-IU vial can be reconstituted and given while the remaining dose is determined and prepared. One of the challenges with using PCCs is their association with increased risk of thrombosis. Combined with a history of VTE, the concern for an additional VTE can be even greater.

In the setting of warfarin, vitamin K can be given orally or parenterally. Parenteral vitamin K has a more rapid onset in INR reduction; however, little difference is seen between the two routes after 24 hours. Recent experiences have suggested that doses greater than 2 mg intravenously provide no additional reduction in the INR after 24 hours, but more prolonged reversal. If the goal is a partial reversal of the INR, low doses of vitamin K (e.g., 0.25–0.5 mg intravenously) can be considered. If anticoagulation is reinitiated shortly, higher doses of vitamin K may lead to prolonged bridge therapy before a response to warfarin occurs. If there is no plan to reinitiate therapy, a vitamin K dose of 10 mg is feasible.

For the newer oral anticoagulants, approaches to reverse their effects have not been established. Dabigatran can be removed by hemodialysis, and given the potential for tissue rebound, prolonged dialysis may be necessary. However, recent availability of an antibody to dabigatran, idarucizumab, may limit the need for hemodialysis. Case reports have suggested that an aPCC can establish hemostasis; however, the optimal dose has not been established. The effectiveness of non-activated PCC is less clear.
For rivaroxaban, edoxaban, and apixaban, any difference between aPCC and non-activated PCC is unclear. Ideally, the lowest effective dose necessary to establish hemostasis may be preferred. If time permits, a lower dose can be used and titrated to effect depending on hemoglobin values and symptoms of bleeding.

Once the bleeding issue resolves, reinitiating anticoagulation may be a consideration. For a previous VTE, obtaining the history of the previous VTE event, including whether it was provoked or non-provoked, the previous number of events, and the duration elapsed, can assist in determining the subsequent management plan. If it has been more than 3 months after a provoked VTE, continued anticoagulation may be unnecessary. In contrast, if there is a history of several non-provoked VTE events, continued therapy may be strongly encouraged.

**CONSIDERATIONS IN SPECIAL POPULATIONS**

Because the critically ill patient is at high risk of VTE, prevention and management decisions continually require assessment each day instead of just during times of admission or transferring between services. Mechanical methods, unless there is a specific reason not to use them, should be used and will be effective as long as they are in use. If anticoagulation therapy is not an option in the presence of a VTE, clinicians may consider temporary placement of an inferior vena cava (IVC) filter. These filters may prevent subsequent PEs, but they have also been associated with a higher rate of VTE; thus, it is preferred that they be removed once it is safe to do so. Decisions to initiate systemic anticoagulation in the presence of an IVC filter should include the plan for filter removal.

The dynamics of a critically ill patient can also continuously be changing between degrees of instability and more stable conditions. The dynamics of other patients, although requiring ICU-level care, can be for the most part very stable, and response to therapy may be consistent with the post-ICU setting. In the unstable patient, decisions on pharmacologic therapy should include the current risk of bleeding.
and thrombosis as well as any trends or future events that may alter
them. In addition, decisions should include timely assessment of the
patient’s clinical presentation such as improving or declining trends,
together with trends in organ function. Assessing such trends in today’s
management decisions will help clinicians achieve goals in subsequent
days.

</table>
For acute decompensated heart failure or notable hypotension, poor perfusion to the kidney or liver may lead to reduced drug clearance and increased levels of anticoagulation and lower dosing requirements. Reductions in the liver’s capacity to produce clotting factors may also occur. Acute and transient changes in response to warfarin may be seen with an infection or new interacting drug added. As the transient influencing factors such as heart function recover or the infection diminishes, drug elimination will recover, and dosing may need to be increased. For such situations with warfarin, for example, and with a desire to sustain its effects, the INR may be notably elevated and dosing held or reduced. As the INR begins to drop, the dosing should be reinstituted or increased before the INR drops to the target range. Holding warfarin until reaching target range after several days of low or no doses may result in a continued drop below target range and require bridge therapy, especially if there was a recent VTE event. Bedside observations and timely assessment of the patient’s clinical presentation, including shifts in factors influencing decisions for management trends in advance, may allow earlier adjustments and minimize time outside the treatment goals.

Acute changes in renal function can alter the dynamics of anticoagulation therapy as well as the balance between bleeding and thrombosis for many factors. Unfortunately, patients with severe forms of renal failure or the requirements for renal replacement therapy have
been poorly studied and excluded from large clinical trials. Dosing of renally influenced agents as noted earlier can also be difficult to manage when kidney function is unstable. Having the ability to measure the level of anticoagulation, if available, may assist in assessing the regimen. In this setting, heparin therapy may be considered because the kidney does not alter its elimination. However, at times, it may not be feasible to use heparin if there is no intravenous access or ability to measure. One option recently explored and included for acutely ill patients requiring hemodialysis was enoxaparin dosed at about 0.6–0.7 mg/kg daily. Anti-Xa activity was not measured in this analysis because it may not accurately describe the balance between thrombosis and hemostasis effects of enoxaparin in this setting as other drivers notable in renal failure may influence outcomes. Anticoagulation in acute liver injury and/or failure, including chronic conditions, can be difficult to manage, not only because of altered effects of the drugs and some assays but also between the balance of thrombosis and the bleeding potential. Although indicators such as the INR may suggest poor clotting factor production and a hypocoagulable state, other factors such as the natural anticoagulants may also be impaired. Management decisions must carefully weigh this. In some cases, acute reductions in liver function could also be caused by portal thrombosis, which would require a separate management approach. When initiating warfarin in the setting of an elevated INR, it has not been established what the subsequent target range should be, and this is typically determined on a case-by-case basis. Use of newer anticoagulants in severe liver impairment is unclear because this population was excluded.

When initiating warfarin in an unstable setting such as liver disease or other factors that may suggest an increased response to a dose, consider allowing as much time as possible between the dose and the subsequent INR to unmask the sensitivity. Remember that when the INR is abruptly rising, it is mainly being driven by a fall in factor VII instead of factor II. As such, the INR may suggest a higher level of anticoagulation than truly exists.

Anticoagulation management decisions relative to invasive
procedures should consider the risk of thrombosis and bleeding before, during, and after surgery. In the pre-operative setting, a bridge to a shorter-acting agent may be considered if the VTE risk is high. Heparin can typically be turned off several hours before the procedure. For LMWH, the last dose may be 24–48 hours prior, and for warfarin, the INR may be allowed to drop to a predetermined level on the basis of bleeding assessments. For other anticoagulants, holds may depend on the perceived time for effects to diminish. If neuroaxial anesthesia is being considered, a longer hold of the anticoagulant to allow the complete absence of anticoagulation may be preferred. This may be used for up 5 days for some agents if their effects cannot immediately be reversed.

Postprocedure management decisions should consider outcomes of the procedure and potential complications or requirements for additional procedures. Anticoagulation may be initiated slowly after procedures with higher risks for bleeding, especially if the CNS or other critical areas are involved when there is no drain in place or ability to transfuse. In some situations, such as in the eye, heart, or spine, a small amount of blood can be devastating. Once bleeding risks subside, either prophylaxis or full anticoagulation therapy can be initiated. With the exception of reinitiating warfarin, bridging between agents is unnecessary.

In some situations, other indications for anticoagulation may be present. In these settings, target ranges or doses may be considered, typically using the higher of the two variables unless there is a bleeding-related issue suggesting the lower intensity. For some of the agents approved for use in VTE, the anticoagulant may need to be switched to an agent that has been determined to be effective in both settings.

HEPARIN-INDUCED THROMBOCYTOPENIA

Immune-mediated HIT is a rare complication associated with exposure to heparin or LMWH that can lead to venous and arterial thrombosis or death. Heparin-induced thrombocytopenia can occur in three time
settings: immediate exposure (within minutes with recent previous exposure to heparin), typical exposure (5–10 days after exposure to heparin), and delayed exposure (up to 40 days after heparin exposure). Because of delayed-onset HIT, patients presenting with acute thrombosis and recent heparin exposure should have their platelet count checked before initiating heparin or LMWH. The presence of antibodies related to immune HIT can be determined using selected assays as a means of separating this from other causes of thrombocytopenia. Common assays include the enzyme-linked immunosorbent assay and the serotonin release assay, which is more specific but may take longer for results to be reported. The process of ordering a test for HIT and for knowing when alternative therapy should be initiated creates notable decisions on how to proceed with anticoagulation management. When making decisions to test for HIT, consider the impact of results because there is the potential for false-positive observations. Because thrombocytopenia for many reasons can occur in the critically ill patient, clinicians should carefully think about adding in HIT testing as part of a global approach to determining the cause for the low platelet count unless clinical suspicion is sufficient. Commonly used HIT predictive tools such as the 4T score include the magnitude of the platelet count drop, timing in relation to heparin exposure, presence of new thrombosis after initiating heparin, and absence of other causes of thrombocytopenia. Platelet counts can commonly drop post-cardiopulmonary bypass surgery, and here, the pattern for HIT is the presence of platelet count recovery, followed by a second drop in platelet count. Other common devices in the ICU such as aortic balloon pumps can commonly cause thrombocytopenia and are not suggestive of HIT.

For HIT, alternative anticoagulation with a DTI or fondaparinux is suggested. Holding heparin or LMWH alone is not recommended. Once platelet counts are sufficiently recovering or have recovered, warfarin can be considered for prolonged anticoagulation. The parenteral anticoagulant should be continued until the INR adjusted for any assay influenced by the DTI is greater than 2.0. At times in the ICU, other causes of thrombocytopenia may be present, and platelet counts may
not recover, resulting in a prolonged course of parenteral anticoagulation.

Alternative anticoagulation in the setting of isolated HIT should be continued until the platelet count has recovered and the risk of thrombosis is resolved. For thrombosis, either as the reason for initial anticoagulation or for thrombosis attributed to HIT (heparin-induced thrombocytopenia thrombosis or HITTS), anticoagulation should be continued for at least 3 months. Given that the antibody response driving HIT is transient, lasting for around 3 months, alternative anticoagulants such as fondaparinux or a DTI may be considered. Such decisions should weigh the risks involved. If transitioning the patient to warfarin, current observations encourage continuing the initial parenteral therapy until the INR is in a target range adapted to the false elevation caused by the DTI. This can be determined by looking at the INR on the DTI before initiating warfarin and adding the elevation to the INR target. For example, if the INR on argatroban is 2.0 before initiating warfarin, an INR above 3.0 should be observed before discontinuing the DTI. Minimal change in the DTI dose between the two INR determinations would be preferred to limit changes in the DTI effect in the INR.

Caution should be exercised against dosing that leads to having excessive effects from warfarin during initiation of therapy because it may pose a risk of venous limb gangrene. In addition, guidelines suggest waiting for the platelet count to recover to more than 150,000/mm$^3$. However, in the critically ill patient especially, platelet counts may not recover, resulting in prolonged DTI therapy. One recent observation noted no difference between the strategies of waiting for platelet count recovery compared with initiating warfarin in conservative dosing once two consecutive rising platelet counts had occurred.

LEARNING OBJECTIVES

1. Describe the physiologic integration of coagulation, fibrinolysis, platelets, and the vessel wall to achieve optimal hemostasis.

2. Delineate the extrinsic and intrinsic coagulation pathways, and compare the common laboratory values used to measure their activities.

3. Define coagulopathy and thrombocytopenia, and outline common etiologies of both in critically ill patients.

4. Explain the pathophysiologic mechanisms contributing to coagulopathy for hypothermia, acidosis, dilutional, inflammation (disseminated intravascular coagulopathy), hepatic dysfunction, renal dysfunction, inherited abnormalities, and medications.

5. Formulate a treatment plan and goals of therapy for fluid resuscitation during hemorrhage.

6. Compare and contrast the blood products (red blood cells, platelets, fresh frozen plasma, prothrombin complex concentrates, and cryoprecipitate) with respect to indications,
goals of therapy, and adverse events.

7. Compare and contrast the pharmacologic agents (local hemostatics, vitamin K, recombinant activated factor VII, desmopressin, conjugated estrogen, and fibrinogen concentrate) with respect to indications, goals of therapy, and adverse events.

8. Develop a plan for the prevention and management of hemorrhage associated with surgery, trauma, hepatic dysfunction, obstetric, and anticoagulants.

INTRODUCTION

Hemostatic pathways act to promote and maintain blood flow. Coagulation is an orchestration of interactions between blood vessels, procoagulant mediators, anticoagulant mediators, and platelets. Several etiologies may disrupt these homeostatic processes, leading to hemorrhage. The clinician must understand these pathologic causes in order to facilitate appropriate management and monitoring. Therapies may include blood products, pharmacologic agents, and nonpharmacologic interventions, each with their own considerations that must be understood to optimize treatment and prevent further hemorrhage. This chapter will review the common causes of disruption to the hemostatic pathways; delineate the properties of blood products, pharmacologic agents, and nonpharmacologic interventions that clinicians need to consider when applying them in a clinical scenario; and discuss appropriate management for common types of hemorrhage.

AN OVERVIEW OF HEMOSTASIS

Hemostasis is a complex homeostatic system that integrates coagulation, fibrinolysis, platelets, and the vessel wall to limit hemorrhage and prevent thrombus propagation. Under normal
conditions, the endothelial cells have antithrombotic properties such as heparin-like glycosaminoglycans, platelet inhibitors, coagulation inhibitors, and activators of fibrinolysis. In contrast, the subendothelium is highly thrombotic with mediators that include collagen, von Willebrand factor (vWF), and platelet adhesion molecules. This hemostatic balance, however, may be disrupted by pathological conditions such as trauma/surgery, blood abnormalities, or inflammation.\(^1,2\)

Any vascular insult results in arteriolar vasospasm, mediated by reflex neurogenic mechanisms and the release of local mediators like endothelin and platelet-derived thromboxane A\(_2\). Platelets are disc shaped and normally do not adhere to intact vascular endothelium. Vessel injury releases vWF, a glycoprotein (GP) always present to some degree in plasma, to cause platelets to undergo a morphological change that increases their surface area. von Willebrand factor also promotes platelet adhesion by acting as a bridge between endothelial collagen and platelet surface receptors GPIb. After adhesion, platelets are activated and undergo degranulation that causes the release of P-selectin; factors I (also called fibrinogen), V, and VIII; platelet factor IV; platelet-derived growth factor; tumor growth factor α; adenosine triphosphate (ATP); adenosine diphosphate (ADP); calcium; serotonin; histamine; and epinephrine. Hypoxia from blood loss or other causes up-regulates P-selectin and can initiate coagulation through the recruitment of factor III (also called tissue factor) containing monocytes. Calcium binds to phospholipids to provide a surface for the assembly of various coagulation factors. Thromboxane A\(_2\) and ADP stimulate further platelet aggregation leading to the formation of a platelet plug, which temporarily seals the vascular injury. Adenosine diphosphate binding also causes a conformational change in GPIIb/IIIa receptors on the platelet surface leading to the deposition of fibrinogen and platelet clumping. Thrombin generation catalyzes the conversion of fibrinogen to fibrin, which stabilizes the platelet plug by forming a matrix for additional adhesion.\(^1,2\)

Comprehending the tissue factor pathway (extrinsic pathway) and the contact activation pathway (intrinsic pathway) is necessary to understand the coagulation cascade, the possible disorders associated
with major hemorrhage, and the laboratory values that describe coagulation and define coagulopathy (Figure 24.1).\textsuperscript{1,2} Most clotting factors are precursors of proteolytic enzymes and circulate in an inactive form. With the exception of tissue factor and factors IV and VIII, clotting factors are produced in the liver. Factors II (also called prothrombin), VII, IX, and X undergo post-translational modification by vitamin K–dependent carboxylation of the glutamic acid residues. Naturally occurring anticoagulants include antithrombin (which inactivates thrombin and factors IXa, Xa, XIa, and XIIa), tissue factor plasminogen inhibitor, proteins C and S, thrombomodulin, and protein Z.

The extrinsic pathway is plasma-mediated hemostasis. It is activated by tissue factor that is expressed in the subendothelial tissue and exposed during direct vascular injury, functional injury (activation of circulating tissue factor), hypoxia, malignancy, or inflammation. Tissue factor binds to calcium to activate factor VII (now called factor VIIa), which further activates factors X, V, and II. The intrinsic pathway is a parallel pathway to the extrinsic system. It is initiated by collagen exposure, which activates factor XII, which in turn activates factors XI, IX, and VIII to form tenase complex on a phospholipid surface. The propagation requires calcium, high-molecular-weight kininogen, and prekallikrein. The extrinsic and intrinsic pathways merge at the common pathway where activated factor X, cofactor V, tissue and platelet phospholipids, and calcium form a prothrombinase complex. This complex converts prothrombin to thrombin to cleave fibrinogen to fibrin and activates factor XIII. This leads to the formation of covalent crosslinks of fibrin (polymers) that are incorporated in the platelet plug.\textsuperscript{1,2} The intrinsic pathway also augments thrombin generation primarily initiated by the extrinsic pathway.

Coagulation can be described as four steps: initiation, amplification, propagation, and stabilization. During the initiation phase, the expression of tissue factor from the inured vessel complexes with factor VIIa, which activates factor IX. The tissue factor-VIIa complex represents a bridge between the two pathways as factor Xa activates thrombin. The generation of thrombin is not robust and can be terminated by tissue factor pathway inhibitor. This thrombin is often
called “priming thrombin” because it binds to platelets to activate them and factors V and VIII, the latter of which serves as a cofactor in the prothrombinase complex and accelerates the formation factor Xa. This process represents amplification. Propagation occurs when the accumulated enzyme complexes (tenase and prothrombinase) on the platelet surface produce robust thrombin, often called a thrombin burst, which further activates platelets creating a positive loop. This ensures continuous thrombin generation and fibrin production in sufficient amounts to form a stable clot. Stabilization is the factor XIIIa process of forming covalently linked fibrin polymers that provide strength to the platelet plug. Thrombin also activates thrombin activatable fibrinolysis inhibitor, which protects the clot from degradation.\textsuperscript{1,2}

\textbf{Figure 24.1} Coagulation cascade delineating the intrinsic, extrinsic, and common pathways.\textsuperscript{1,2}

\textbf{Measuring Hemostasis}

To fully comprehend the limitations of treatments used to promote
hemostasis, it is necessary to understand the assays used to measure coagulation (Figure 24.1). The prothrombin time (PT) and the international normalized ratio (INR) monitor the extrinsic pathway (tissue factor pathway) and common portions of the clotting cascade. Platelets are removed from citrate anticoagulated plasma by centrifugation to isolate the role of the soluble clotting factors to which tissue factor and calcium are added to initiate clotting. This process preferentially activates factor VII, which in turn activates factors X, V, and II to ultimately convert fibrinogen to fibrin; this last step is captured optically or electrically and measured in seconds. Because factor VII circulates in the highest abundance of any factor, the PT is relatively resistant to change and requires single factor levels to decline to less than 10% of normal before becoming prolonged. The only factor unique to this pathway is factor VII, so the only manner in which PT can be prolonged without affecting PTT is a selective factor VII deficiency. The PT is commonly referenced to an international standard (INR) because the sensitivities of the reagents measuring PT vary. The INR is calibrated to assess anticoagulation in patients receiving stable warfarin therapies. Its applicability to other causes of an elevated PT is uncertain, although commonly done. In hepatic dysfunction, the extent of coagulopathy as measured by the PT or INR is not predictive of bleeding complications. Normal values for PT and INR are 12–13 seconds and 0.8–1.2, respectively.

The activated partial thromboplastin time (aPTT) measures the intrinsic pathway and is more complex than the PT. A particulate contact activator (hence the name “activated”) like ellagic acid, kaolin, celite, or silica is added to platelet-poor citrate anticoagulated plasma to which a “partial thromboplastin” (lacking tissue factor) is added and the citrate reversed with calcium. The particulate activates factor XII, which in turn activates factors XI, IX, and VIII and the common sequence of factor X through fibrin formation. Like PT, aPTT is measured in seconds with normal reference values of 25–35 seconds, but unlike PT, single factors unique to the aPTT must decline to only 15%–30% of normal values for the aPTT to be prolonged. This may reflect the lengthier clotting sequence contributing to the aPTT and/or
the fact that these clotting factors are already lower in concentration than factor VII. Milder deficiencies of many factors can prolong the aPTT, so it may be more sensitive than PT for assessing factor changes, especially factors VIII and IX. Prekallikrein, high-molecular-weight kininogen, antiphospholipid antibodies, and factor XII deficiencies prolong aPTT, but none increases the risk of hemorrhage.

Other tests used to measure coagulation include anti-Xa activity, activated clotting time, and assessments of fibrinolysis. Anti-Xa activity is often used to assess anticoagulation in patients receiving low-molecular-weight heparins, especially in patients at the extremes of weight or those with reduced or increased kidney function. Activated clotting time nonspecifically measures the time for an activating agent to produce clot in whole blood and is often used to monitor unfractionated heparin or direct thrombin inhibitors (DTIs) during surgery. Fibrinolysis is the process of dispersing and dissolving clot. This process may be described by the term fibrin degradation product or D-dimer. The fibrin degradation product assay refers to the breakdown products of fibrin and fibrinogen produced by plasmin. The nonspecific fibrin degradation product or fibrin split product assay may be present in the absence of clot. In contrast, the D-dimer is only formed from the degradation of fibrin from an intact clot. Both assays lack specificity and are commonly positive in critically ill patients regardless of the presence of thromboembolic disease or coagulopathy. In addition, fibrin degradation product and D-dimer are hepatically eliminated, so liver function may influence their specificities. Moreover, various commercially available assay methods differ significantly (e.g., latex or red blood cell [RBC] agglutination, enzyme-linked immunoassays) resulting in varying sensitivities. Normal values for D-dimer are below 500 ng/mL.

**Measuring Platelet Function**

Platelet function may be assessed for a variety of reasons including identifying bleeding disorders, monitoring response to antiplatelet therapies, evaluating perioperative hemostasis, and guiding platelet
transfusion therapy.\textsuperscript{5,6} Several tests are available to assess platelet function and include light transmission platelet aggregation, impedance aggregometry on whole blood, lumi-aggregometry, platelet activation by flow cytometry, and shear stress platelet activation.\textsuperscript{5,6} Light transmission platelet aggregation is considered the gold standard test and incorporates in vitro platelet-to-platelet clump formation in a GPIIb/IIIa-dependent manner. The assay measures the light transmission after platelet-rich plasma is activated with various platelet agonists (e.g., collagen, ADP, thrombin, epinephrine, arachidonic acid). Light transmission increases as platelets aggregate. Although this method can assess different platelet aggregation pathways and is sensitive to antiplatelet therapy, it is time-consuming and not reflective of whole blood activity because it uses platelet-rich plasma. It also requires relatively large volumes of blood to generate platelet-rich plasma. Impedance aggregometry, which uses smaller volumes of citrated whole blood, is based on the principle that activated platelets stick by their surface receptors to artificial surfaces of electrodes within the sample. Electrical impedance is generated by aggregated platelets, which is measured by diminishing current between electrodes. This method is available as point-of-care testing and is sensitive to antiplatelet therapy. Lumi-aggregometry measures the ATP released from platelets that are activated in vitro by various agonists. The ATP reacts with a luciferin-luciferase reagent, and the intensity of light emitted is proportional to the ATP concentration. This method may be used to assess several platelet aggregation pathways and is particularly useful for assessing platelet function when thrombocytopenia is present. Flow cytometry, which uses citrate anticoagulated whole blood, is based on the optical and fluorescence evaluation of the physical and antigenic properties of platelets. Therefore, it assesses the internal complexity and conformational changes of platelets in response to in vitro platelet activation. Antibodies that bind to specific proteins on the platelet surface or inside the platelet are conjugated to fluorescence dyes so that light is emitted on platelet activation. The results are expressed as a histogram with fluorescence intensity plotted against platelet number. This method is
sensitive to antiplatelet therapy and may be used when thrombocytopenia is present. Shear stress platelet activation applies physical stress to citrate anticoagulated whole blood and measures either the time taken for platelets to occlude a collagen-coated orifice or the percentage of a polystyrene plate covered by platelet aggregates. This method is available as point-of-care testing and is sensitive to antiplatelet therapy.

COAGULOPATHY AND THROMBOCYTOPENIA IN CRITICALLY ILL PATIENTS

Hemostatic abnormalities are common in critically ill patients, ranging from an isolated laboratory abnormality to complex derangements. By far the most common causes of abnormal clotting assays and low platelet counts are errors incurred during sample collection or laboratory analyses, so laboratory aberrations should always be confirmed, especially in the absence of clinical manifestations. As discussed in the previous section, coagulation and hemostasis require complex interactions between the vessel wall, platelets, and soluble coagulation factors. Hemostatic abnormalities can result when any one of these three systems is defective. However, several causes may contribute to the mechanisms of abnormal hemostasis, making it difficult to diagnose and manage hemostatic derangements in critically ill patients.7-10

Coagulopathy

Alterations in coagulation factors, including decreased levels of coagulation factors, reduced levels of endogenous anticoagulants, and enhanced fibrinolysis, all contribute to hemostatic abnormalities in critically ill patients.7-10 Despite their poor reflection of in vivo hemostasis, laboratory values such as aPTT, PT or INR and platelet counts are often used to assess the degree of coagulopathy (Table 24.1).3,4,7-11 Up to one-third of patients in the intensive care unit (ICU) have coagulopathy, as defined by an INR of 1.5 or greater or an aPTT
of 1.5-fold or greater than the upper limit of normal.\textsuperscript{10} The presence of coagulopathy increases the likelihood of hemorrhage by 4- to 5-fold and is an independent risk factor for mortality (odds ratio [OR] 1.5–4.3).\textsuperscript{12} Causes of coagulopathy are generally categorized by the extent that either or both the PT/INR and the aPTT are prolonged (Table 24.1).\textsuperscript{3,4,7-11} Mechanisms contributing to coagulopathy include hypothermia, acidosis, dilution from administration of fluids and blood products, disseminated intravascular coagulation (DIC), liver dysfunction, renal dysfunction, inherited disorders, and medications.\textsuperscript{4,7-11}

**Hypothermia**

Hypothermia may be the result of several causes, including iatrogenic etiologies such as therapeutic hypothermia, surgery, or invasive interventions (e.g., dialysis, extracorporeal membrane oxygenation, plasmapheresis) or non-iatrogenic etiologies such as prolonged exposure to cold ambient temperatures, impaired thermoregulation (e.g., injuries to the central nervous system, hypothyroidism), or excessive heat loss (e.g., thermal injuries, drug intoxication).\textsuperscript{12} The mechanisms of hypothermia-induced coagulopathy vary with the magnitude of hypothermia, and the extent of coagulopathy grows exponentially as the core body temperature decreases.\textsuperscript{13} Although temperatures of 35°C and greater have very little effect on coagulation, temperatures of 32°C–34°C alter platelet number and function by reducing platelet adhesion and aggregation.\textsuperscript{14,15} Temperatures of 33°C or less decrease the synthesis and kinetics of coagulation factors.

Therapeutic hypothermia to temperatures of 32°C–34°C for up to 24 hours may improve neurologic recovery in comatose patients with the return of spontaneous circulation after cardiac arrest.\textsuperscript{16} The occurrence of bleeding requiring transfusions in the setting of therapeutically-induced hypothermia is 6%.\textsuperscript{17} The risk of hemorrhage should not be viewed as a reason to withhold therapeutic hypothermia treatment in patients who are not actively bleeding. In patients who are at high bleeding risk or are actively bleeding, the hemorrhage risk should be considered in the context of possible neurologic benefit.\textsuperscript{17} Hypothermia
should be reversed and core body temperatures maintained at 35°C or greater when hypothermia is the result of other iatrogenic or non-iatrogenic etiologies.

DIC = disseminated intravascular coagulopathy; DTI = direct thrombin inhibitor.

**Acidosis**

Acidosis is a common clinical problem in critically ill patients and is a known predictor of coagulopathy in the ICU. Acidosis can present as a result of both respiratory and metabolic disturbances; however, coagulopathy is often caused by a hypoperfused state resulting in increased lactate generation. Coagulopathy is heightened when hypothermia is also present as acidosis and hypothermia synergistically impair coagulation.$^{18,19}$ The clinical effects include both prolonged clotting times and increased bleeding times, with a direct correlation
The mechanisms of acidosis-induced coagulopathy primarily involve severe inhibition of the propagation phase of thrombin generation and increased fibrinogen degradation. However, clotting factor function is also significantly impaired because acidic environments hinder protease activity and limit anion exposure of phospholipids. When pH drops below 7.2, the functional activities of factor VIIa, tissue factor-factor VIIa complex, and the factor Xa/Va complex are diminished. As a result, clotting time is prolonged, and overall clot strength is weakened. Although few studies have reported on outcome assessments looking strictly at acidosis-induced coagulopathy, it is usually regarded as a poor prognostic sign. It is common practice before giving procoagulants to ensure that pH values are 7.2 or greater by temporarily inducing hyper-ventilation or administering intravenous bicarbonate.

Dilutional
Critically ill patients often require rapid resuscitation with large volumes of crystalloids, colloids, or RBCs if critical bleeding is present. As a result, these patients often have dilutional coagulopathy, a combination of decreased plasma concentrations of coagulation factors and platelets. The degree of coagulopathy is directly related to the total volume transfused, in addition to preexisting hemostatic abnormalities, and the effects are synergistic with coagulopathy from hypothermia and acidosis.

Dilutional coagulopathy is the result of an uncompensated loss of platelets and coagulation factors. This occurs most commonly during situations involving major blood loss or large-volume resuscitation, but it can also occur in critically ill patients with increased consumption or sequestration of platelets. Red blood cell concentrates contain negligible amounts of platelets and coagulation factors, so they can further exacerbate a patient’s risk of developing dilutional coagulopathy when transfused in large quantities. A platelet count of less than $50 \times 10^9/L$ is expected when two blood volumes have been replaced by fluid.
Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy is an acquired syndrome characterized by systemic intravascular activation of coagulation that can occur in up to 25% of critically ill patients.\(^7,23\) It originates secondary to fibrin deposition and intravascular microthrombi and may lead to significant complications including major bleeding and multi-organ dysfunction.\(^10,24\) Critically ill patients with DIC often have rapidly decreasing platelet counts, low plasma concentrations of coagulation factors, prolonged coagulation tests, increased markers of fibrinogen formation, and hyperfibrinolysis. These abnormalities often lead to bleeding as the first sign of DIC, with only 5%–10% of cases presenting with microthrombi alone.\(^7\) A DIC scoring tool developed by the International Society on Thrombosis and Haemostasis assigns points according to the extent of thrombocytopenia (platelet counts of 50–100 \(\times 10^9\)/L = 1 point, platelet counts less than 50 \(\times 10^9\)/L = 2 points), fibrin concentrations (moderate rise = 2 points, strong rise = 3 points), PT prolongation (3–6 seconds = 1 point, greater than 6 seconds = 2 points), and fibrinogen concentrations (less than 100 mg/dL = 1 point).\(^5\) A score of at least 5 points in the presence of an underlying disorder associated with DIC is indicative of DIC.\(^5,23,24\)

There are several etiologies of DIC among critically ill patients, with the most common cause being sepsis, followed by systemic infection, trauma, surgery, malignancy, thermal injury, and pancreatitis.\(^9,24\) Less common etiologies include immunologic reactions (e.g., transplant rejection, host vs. graft disease, transfusion reactions, venomous bites...
or stings), vascular abnormalities, and cardiopulmonary bypass. The mechanism of DIC is multifactorial but is commonly mediated by pathogen-associated molecular patterns and the generation of an overwhelming inflammatory response. Proinflammatory cytokines activate mononuclear cells and endothelial cells, which in turn express tissue factor, the main initiator of the extrinsic pathway of coagulation. The physiological anticoagulation mechanism and endogenous fibrinolysis are stimulated but are inadequate to counterbalance the thrombin generation and intravascular fibrin formation. This, in combination with continuous consumption of platelets and clotting factors, leads to multiorgan failure and severe bleeding complications. Treatment with anticoagulants (e.g., heparin, DTIs) may be attempted, but this often hastens the development of hemorrhage. Instead, therapies usually focus on preventing hemorrhage and reversing the underlying disorder causing the proinflammatory state.

Hepatic Dysfunction

Hepatic insufficiency is the most common cause of acquired coagulation abnormalities. Thrombopoietin and most hemostatic proteins are synthesized in the liver; thus, reduced hepatic function often results in prolonged coagulation tests. Splenic sequestration of platelets can also occur, further contributing to thrombocytopenia. Recent data suggest that patients with hepatic insufficiency are not naturally “auto-anticoagulated,” as once believed. Therefore, these patients may be at increased risk of both hemorrhage and thrombosis.

The coagulopathy abnormalities seen in patients with hepatic insufficiency are complex. Anticoagulation occurs because hepatic synthesis of coagulation factors II, V, VII, IX, and X is reduced, the metabolism of tissue plasminogen activator is impaired, and fibrinogen production is lessened. In addition, moderate to severe vitamin K deficiencies can occur in hepatic insufficiency. In contrast, levels of factor VIII and vWF, potent drivers of thrombin generation, are
increased to enhance coagulation. In addition, there is a concomitant reduction in endogenous anticoagulants (proteins C, S, and Z; antithrombin; and Z-dependent pro-tease inhibitor) and fibrinolytic mediators (thrombin activatable fibrinolysis inhibitor) that enhance coagulation and clot stability.\textsuperscript{7,9,11} Thus, patients with hepatic insufficiency and prolonged coagulation tests may not be at increased bleeding risk.\textsuperscript{3,12,26,27} Because discerning the likelihood of hemorrhage is clinically impossible, most clinicians try to minimize the extent of the coagulopathy before invasive procedures or during a bleeding event. It is plausible that bleeding in patients with hepatic insufficiency is the result of other etiologies of coagulopathy acquired from the acute situation (e.g., a systemic infection causing DIC).

**Renal Dysfunction**

Kidney failure produces uremia-induced qualitative defects in platelets that arise from insufficient vWF, decreased production of thromboxane A\textsubscript{2}, increased cyclic adenosine monophosphate and cyclic guanosine monophosphate, and anemia.\textsuperscript{7,27} In addition, the quantity of GPIIib receptors on platelet surfaces is diminished. Platelet function is improved with dialysis.\textsuperscript{27,29} The anemia that commonly accompanies renal disease reduces ADP production and diminishes laminar flow in the vasculature, which hampers platelet and clotting factor migration, ultimately leading to prolonged clotting times and coagulopathy. Treatment of the anemia with erythropoiesis-stimulating agents or the administration of RBC transfusions helps reverse the coagulopathy.\textsuperscript{27,29} Renal dysfunction also leads to impaired fibrinolysis and reduced generation of factor VIII–related antigen, impairing both clot breakdown and formation, respectively.\textsuperscript{27,29}

**Inherited Abnormalities**

Consideration should be given to an inherited bleeding disorder if unexplained coagulation abnormalities are present in a critically ill patient.\textsuperscript{1,7} Although uncommon, hemophilia and von Willebrand disease can pose significant bleeding complications among critically ill
Hemophilia A is characterized by deficiencies in factor VIII, whereas hemophilia B is characterized by deficiencies in factor IX. Both disorders are inherited X-chromosome–linked conditions that range in severity from mild surgery or trauma-related bleeding to severe spontaneous bleeding into muscles and joints.\textsuperscript{1,7} Acquired hemophilia is a rare but potentially life-threatening bleeding disorder caused by the development of autoantibodies (inhibitors) directed against plasma coagulation factors, most commonly factor VIII. In general, spontaneous bleeding occurs only in cases with less than 2% of coagulation factors.\textsuperscript{27} However, patients with greater than 10% of coagulation factors may be at risk of excessive hemorrhage after trauma, surgery, or other invasive procedures.\textsuperscript{27} von Willebrand disease is characterized by a deficiency in vWF, which plays an essential role in both platelet adhesion and binding to factor VIII to prevent rapid degradation of factor VIII.\textsuperscript{1,11} Other rare congenital disorders that lead to coagulation abnormalities include factor V Leiden deficiency, factor XI deficiency (also known as Rosenthal syndrome or hemophilia C), factor VII deficiency, prothrombin deficiency, fibrinogen disorders, and plasminogen activator inhibitor deficiency.\textsuperscript{1,9}

**Medications**

Coagulation abnormalities can also occur in critically ill patients taking or receiving medications that alter the coagulation cascade or interfere with platelet function. Therapeutic anticoagulation with agents such as unfractionated heparin, low-molecular-weight heparins, warfarin, anti-Xa inhibitors, and/or DTIs inhibits coagulation and increases a patient’s risk of bleeding.\textsuperscript{7,30,31} In addition, fibrinolytic medications or medications that interfere with platelet aggregation can alter a patient’s ability to maintain hemostasis (Table 24.2).\textsuperscript{7,11,12,30-33} Anticoagulants, platelet inhibitors, and fibrinolytic agents are commonly administered to patients for therapeutic reasons or to prevent clot formation during surgical procedures (e.g., cardiopulmonary procedures) or when invasive devices (e.g., dialysis, extracorporeal membrane oxygenation) are used.\textsuperscript{30-33}
Thrombocytopenia

Thrombocytopenia in the ICU ranges from 15% to 60%, depending on the definition used and the population evaluated, with trauma/surgery patients having a higher prevalence than medical patients.\textsuperscript{7,34} Thrombocytopenia is typically defined as a platelet count less than 150 × 10\textsuperscript{9}/L or a decrement of 50% or greater from a recent previous measurement.\textsuperscript{35-37} The presence of platelet counts less than 50 × 10\textsuperscript{9}/L increases the likelihood of hemorrhage by 4-to 5-fold and is an independent risk factor for mortality (OR 1.9–4.2).\textsuperscript{34-37} The incidence of spontaneous hemorrhage, however, is low for patients with a platelet count exceeding 10 × 10\textsuperscript{9}/L.\textsuperscript{35} Although fewer than 5% of ICU patients develop platelet counts of 20 × 10\textsuperscript{9}/L or less, this value is often used as a threshold to maintain in an effort to prevent hemorrhage.\textsuperscript{34,35} Values of 30–50 × 10\textsuperscript{9}/L are targeted when hemorrhage is present.\textsuperscript{34-37}

\begin{table}[h]
\centering
\caption{Drug-Induced Therapeutic Coagulopathies and Reversal Options\textsuperscript{7,11,12,30-33}}
\end{table}
Platelets participate in hemostasis through several mechanisms, including the release of vasoactive substances (e.g., thromboxane A₂...
and serotonin), activation of the coagulation cascade by releasing attractants for additional platelets (e.g., thromboxane A\textsubscript{2} and ADP), provision of a phospholipid scaffold formed when activated platelets bind to circulating fibrinogen, and adherence and aggregation at the site of injury to form a platelet plug.\textsuperscript{1,35} Causes of thrombocytopenia are generally categorized according to decreased platelet production in the bone marrow, sequestration of platelets in the spleen, or enhanced platelet destruction (immunological or non-immunological, mechanical) (Table 24.3).\textsuperscript{7,8,34-37} Rare inherited platelet disorders include Glanzmann disease and Bernard-Soulier disease.

Screening tests to investigate the source of thrombocytopenia should include a confirmatory platelet count, full blood count with peripheral blood film, coagulation tests, platelet function tests, fibrinogen, B\textsubscript{12}, folate, renal function tests, liver function tests, HIV, hepatitis C, and imaging to examine for the presence of portal hypertension or splenomegaly.\textsuperscript{5,6,8,34-37} Up to 25% of critically ill patients develop drug-induced thrombocytopenia (Table 24.4).\textsuperscript{7,34,35} With the exception of heparin-induced thrombocytopenia, drug-induced causes are etiologies of exclusion that often necessitate careful examination of the daily platelet count profile and the medication administration record.\textsuperscript{7,34,35}

---

**HEMORRHAGE PREVENTION, RESUSCITATION, AND MANAGEMENT**

The prevention of hemorrhage is targeted at avoiding excessive coagulopathy and thrombocytopenia. Although few data exist, the goals of therapy are to lower the INR less than 1.5 and the aPTT less than 1.5-fold the upper limit of normal and maintain platelet counts of 20 × 10\textsuperscript{9}/L or greater.\textsuperscript{1,2,7,8,35-38} Several etiologies exist for coagulopathy and thrombocytopenia, and providing procoagulant therapies may be relatively or absolutely contraindicated in some circumstances (e.g., DIC, cases of immune-mediated thrombocytopenia like heparin-induced thrombocytopenia). In practice, the reversal of coagulopathy and thrombocytopenia to prevent bleeding is similar to the correction of
these during hemorrhage, except that time is of less concern during prevention so that the causative etiology may be investigated and possibly therapeutically targeted, whereas early support of coagulation is required during hemorrhagic resuscitation. Agents used to reverse coagulopathy include vitamin K, FFP, prothrombin complex concentrates (PCCs), and recombinant activated factor VII (rFVIIa). Platelet administration is used to correct thrombocytopenia. Platelet administration is used to correct thrombocytopenia. 

The basic goals of therapy in the management of hemorrhage are achieving fluid resuscitation and bleeding cessation by correcting anemia, reversing coagulopathy, optimizing platelet activity, and inhibiting fibrinolysis, all while minimizing adverse events and bleeding sequelae. Early resuscitation is often characterized by uncertainty regarding the exact source of the bleeding, quantity of blood loss, and anticipated duration of hemorrhage. The manifestations of hemorrhage, however, may be used as a crude estimate of blood loss. Tachycardia and light-headedness are often evident after 15%–30% blood volume depletion, hypotension develops after 30% or greater depletion, and severely altered sensorium usually requires 40% or greater depletion. Initial resuscitation is targeted at rapidly repleting intravascular volume and is commonly performed with the administration of a warmed isotonic crystalloid solution. The initial response to 1–2 L of normal saline indicates the extent of hemorrhage and may help predict the need for additional therapies. The return of normal vital signs suggests the hemorrhage was mild-moderate (estimated blood loss less than 2 L) and likely ceased, so the need for additional resuscitation is unlikely. A transient improvement in vital signs suggests the hemorrhage was moderate (estimated blood loss of 2–3 L) and likely ongoing, so the need for additional resuscitation and blood product administration is probable. Little to no change in vital signs suggests the hemorrhage was severe (estimated blood loss of greater than 3 L) with ongoing active bleeding, so the need for additional resuscitation and blood product administration is immediate. The patients with little to no change in vital signs require emergency medical therapy to treat the etiology of the hemorrhage, necessitating the planning process for many possible interventions by several services
(e.g., interventional radiology, general or specialized surgery services, trauma, gastroenterology, critical care, nursing, pharmacy). In all cases, rapidly controlling the source of hemorrhage must be a priority, and delaying an intervention while obtaining a laboratory or radiological study, placing an invasive monitor, or awaiting other therapies increases the likelihood of exsanguination.

**Fluid Resuscitation**

Initial resuscitation should be administered through a large-bore intravenous catheter using either normal saline or lactated Ringer solutions.\(^{13,42,43}\) Specialty infusion systems provide real-time warming and have high-flow capacities with built-in filters so that resuscitation fluids and blood products can be administered rapidly in emergency situations. Saline solutions may induce hyperchloremic acidosis, whereas lactated Ringer solutions may worsen lactic acidosis or induce hyperkalemia if hepatic impairment or renal dysfunction is present, respectively.\(^{13,42,43}\) Racemic lactated Ringer solutions may be proinflammatory and induce apoptosis. Other resuscitation fluids include hyper-tonic saline solutions and colloid fluids. Hypertonic saline solutions increase transmembrane sodium gradients, may produce more rapid hemodynamic improvement with less cumulative fluid volume than isotonic solutions, and have been shown in rodent models to ameliorate immunodepression.\(^{13,42,43}\) Colloid fluids are usually reserved for patients with moderate hypovolemia without adequate response to crystalloid or showing manifestations of pulmonary or cerebral edema or cardiac overload.\(^{13,42,43}\) Although the Committee on Trauma of the American College of Surgeons recommends lactated Ringer solutions, the choice of fluid will ultimately be guided by local practice patterns, prescriber preferences, and perhaps cost.\(^{12,42}\)

The goals of resuscitation should focus on restoring tissue perfusion and hemodynamic status.\(^{13}\) Although adequate resuscitation should optimize oxygen delivery and stabilize hemodynamic deviations, systolic blood pressures of 80–90 mm Hg should be the goal of resuscitation because the bleeding rate and cumulative blood loss are lessened with
permissive or deliberate hypotension.\textsuperscript{1,41} Overly aggressive fluid resuscitation shifts the Frank-Starling curve to increase cardiac output, which causes a reflex vasodilation, both of which increase blood flow to the injured vasculature to possibly enhance the rate of blood loss. Increased blood pressure may also wash away early clot formation, and the resuscitation fluid will decrease the blood viscosity and dilute clotting factors, RBCs, and platelets at the site of injury.\textsuperscript{11} These reasons may explain the results of a recent systematic review that found liberal fluid resuscitation strategies were associated with higher mortality than restrictive strategies (risk ratio [RR] 1.25; 95% confidence interval [CI], 1.01–1.55) across three randomized trials of trauma patients.\textsuperscript{44} As a result, clinical goals have shifted from the traditional approach of rapid bolus fluid administration to a systematic approach that includes supporting coagulation while providing the least amount of fluid to reverse hemodynamic compromise without overly increasing cardiac output.\textsuperscript{13} Therefore, early resuscitation requires substantial clinical judgment and experience, so management recommendations are guidelines and not standards of care.

Global tissue perfusion may be assessed by blood lactate concentrations with restored perfusion indicated by declining lactate values over minutes to hours because lactate production is a function of anaerobic metabolism in the presence of tissue hypoxia.\textsuperscript{13,42,43} The adequacy of regional perfusion can be assessed by indices of specific organ perfusion. These measurements may include the following:\textsuperscript{13,39-41}

- normalization of coagulation abnormalities,
- improvement in renal dysfunction as indicated by adequate urine production (greater than 0.5 mL/kg/hour) and/or decreasing serum concentrations of blood urea nitrogen and creatinine,
- improvement in hepatic parenchymal dysfunction as indicated by normalizing serum concentrations of transaminases and bilirubin,
- change in extremities from cool and mottled to warm with rapid capillary refill and normalizing temperature gradient
between the toe and core body,
- normalization of elevated troponin concentrations from cardiac ischemia,
- reversal of altered sensorium.

Correction of Anemia

Red blood cell administration is used clinically to increase hemoglobin with the intent of enhancing oxygen-carrying capacity and tissue
perfusion. About 2 units of packed RBCs (PRBCs) are procured from each whole blood donation.\(^2,38\) Packed RBCs are stored at 1°C–6°C in a solution containing citrate, phosphate, dextrose, adenine, and nutrients. Each unit has a shelf-life of 42 days.\(^2,38\)

Major or massive blood loss is defined as a loss of 100% of the circulating blood volume within 24 hours, at least 50% within 3 hours, the transfusion of 6 units of PRBCs in a 12-hour period, or a bleeding rate of 1.5 mL/kg/hour or greater.\(^13\) Clinical practice guidelines recommend maintaining hemoglobin values of 7 g/dL, primarily on the basis of studies of non-bleeding critically ill patients and patients with upper gastrointestinal (GI) hemorrhage. The combined results of these studies found lower mortality rates, fewer cardiopulmonary adverse events, and reduced ongoing hemorrhage in patients allocated to restrictive transfusion strategies aimed at a hemoglobin value of 7 g/dL.\(^39,40,45-47\) Retrospective data from hemorrhaging Jehovah’s Witness patients support limited detrimental outcomes of permissive anemia.\(^46-49\) The transfusion threshold may be increased to 8 g/dL in patients with preexisting cardiovascular disease or active cardiac ischemia.

The decision to transfuse PRBCs must consider intravascular volume status, the presence of shock, the duration and extent of anemia and coagulopathy, cardiopulmonary parameters, and the extent of lactic acidosis. Packed RBCs are usually required only when the estimated blood loss exceeds 1.5–2 L.\(^40,42,47\) In general, hemorrhaging patients should receive a single unit of PRBC at a time with response assessed thereafter; however, the patient with massive hemorrhage or in hypovolemic shock may need several units rapidly transfused simultaneously.\(^3,13,27,47\) In the stable patient of average size, 1 unit of PRBC will elevate hemoglobin by about 1 g/dL or the hematocrit by 3%.\(^47\) Increases less than these thresholds may be the result of dilution from the concomitant administration of crystalloid solutions, or it may indicate ongoing hemorrhage, which warrants further investigation. The process of compatibility testing takes 45 minutes to complete and includes ABO and Rhesus blood typing and antibody screening.\(^27,38\) In emergency situations, O/Rh-negative blood is used without antibody
Several concerns surround PRBC administration. First, many evaluations have failed to show meaningful increases in end-organ oxygen delivery and use despite increases in hemoglobin.\textsuperscript{38} This is contradictory to the common goal of using allogenic administration of PRBCs to enhance tissue perfusion. This contradiction may be explained by the timing of the intervention relative to the onset of hemorrhage. Alternatively, storage of the RBCs may induce biochemical changes in rheology to enhance microcirculatory occlusion and increase hemoglobin’s affinity for oxygen (rapid decline in S-nitrosohemoglobin, 2,3-diphosphoglycerate, and ATP) to reduce oxygen dis-association and promote tissue ischemia.\textsuperscript{38,48}

Allogenic RBC administration may contribute to coagulopathy because RBCs contain citrate, which binds calcium, a cofactor for many clotting factors, and are stored at pH values of 6.5–7 (lactate concentrations increase 15-fold, and pH declines to 6.7 after 3 weeks of storage).\textsuperscript{38} Many transfusion protocols recommend monitoring systemic ionized calcium values and preemptively administering intravenous calcium when 4 units of PRBCs have been given.\textsuperscript{38} Each PRBC unit also provides about 7–10 mEq of potassium because potassium leaks from RBCs during storage.\textsuperscript{38} Allogeneic PRBCs may also promote coagulation by activating host platelets through thromboxane generated by the stored RBC and by producing thrombin in the host in response to phospholipid exposure caused by membrane vesiculation of the stored RBC. A recent study of “fresh” (average storage time of 6.1 ± 4.9 days) versus “old” (average storage time of 22 ± 8.4 days) PRBC transfusions in critically ill patients without hemorrhage showed similar outcomes of mortality, length of stay, transfusion reactions, and duration of organ-specific support.\textsuperscript{49}

Another concern of allogenic RBC transfusions, and other allogeneic blood products, is the profound effects they have on the recipient’s immune function, which contributes to transfusion-related acute lung injury (TRALI) and transfusion-related immunomodulation (TRIM).\textsuperscript{38,50-52} Transfusion-related acute lung injury is defined as new-onset acute lung injury occurring within 6 hours after completing the transfusion of a
plasma-containing blood product. The pathogenesis of TRALI relates to blood products that contain antibodies to the recipient’s human leukocyte antigen or human neutrophil antigen.\textsuperscript{50} Allorecognition leads to the activation of neutrophils that are margined in the lung to cause inflammation and disruption of the lung-alveolar-capillary permeability barrier. Monocytes and activated platelets also contribute. Experimental models have also implicated cell membrane phospholipids, specifically lysophosphatidylcholine, which are generated during storage of cellular blood products and can prime neutrophils. The incidence of TRALI is 1 in 12,000 PRBC transfusions, and the mortality rate is 6%, substantially lower than the estimate for other forms of acute lung injury.\textsuperscript{38,50,51} Excluding females with a pregnancy history as blood donors lowers the TRALI rate by 10- to 20-fold because these females are more likely to have anti–human leukocyte antigen or anti–human neutrophil antigen antibodies given their exposure to fetal blood.\textsuperscript{38,50,51} The process of leukoreduction by specialized filtration or irradiation of donated blood also reduces the likelihood of TRALI. Irradiated blood products are indicated in severely immunocompromised patients or transplant populations where leukocytes are speculated to contribute to graft-vs.-host disease; however, the process reduces RBC viability and increases the release of intracellular potassium. Leukocyte-reduced blood components contain less than $5 \times 10^6$/L of leukocytes. Around 70% of transfused PRBCs are leukoreduced in the United States.\textsuperscript{50,51}

Transfusion-related immunomodulation refers to a state of proinflammation and immunosuppression associated with transfusions of allogeneic blood products. The pathogenic mechanism is still speculative, but the process is likely mediated by allogeneic mononuclear cells, white blood cell–derived soluble mediators, and soluble human leukocyte antigen peptides circulating in allogeneic plasma.\textsuperscript{38,50-52} During RBC storage, cytokines and inflammatory mediators such as interleukin (IL)-1, IL-6, and tumor necrosis factor also accumulate and may contribute to the pathogenesis of TRIM. Transfusion-related immunomodulation likely contributes to the association of the administration of blood products with acquired
infections and organ failures. Leukoreduction of donated blood decreases the likelihood of TRIM.

Transfusion-associated cardiac overload (TACO) is acute pulmonary edema secondary to congestive heart failure precipitated by the volume of fluid in transfusions that overwhelm the recipient’s circulatory system. Risk factors for TACO include both the total volume and the transfusion administration rate, number of blood products administered, preexisting fluid balance, renal dysfunction, preexisting cardiac dysfunction, and extremes of age. Transfusion-associated cardiac overload is not as prevalent as TRALI but is associated with higher morbidity and mortality. Other concerns of PRBCs include hemolytic reactions from the transfusion of mismatched blood products caused by the recipient’s complement antibodies attaching to donor RBC antigens, fevers and rigors associated with nonhemolytic immunological responses, other allergic reactions like urticaria and anaphylaxis, and the transmission of infectious diseases (HIV risk is 1 in 2 million units; hepatitis B, C, and A risks are each 1 in 250–500,000 units).

Costs of PRBCs vary depending on what expenses are included, but estimates per unit range from $250 as a rudimentary approximation to $750 when all costs associated with donation and procurement, processing, storage, matching, preparation, and administration are included.

Reversal or Prevention of Coagulopathy

The presence of coagulopathy is an independent risk factor for mortality during hemorrhage, and many factors may contribute to its development. The general goals for reversing coagulopathy are an INR less than 1.5, an aPTT less than 1.5-fold the upper limit of normal, platelet count of $30–50 \times 10^9/L$ or greater (or $20 \times 10^9/L$ or greater to prevent hemorrhage), optimizing platelet function, fibrinogen of 100 mg/dL or greater, arterial pH of 7.20 or greater, core body temperature of 35°C or greater, and normal blood values of ionized calcium. Several agents are available that may be tried to reverse prolonged clotting times (Table 24.5 and Table 24.6). These include
Vitamin K

Vitamin K₁, also known as phytonadione or phylloquinone, is a fat-soluble compound that aids in the carboxylation of glutamate residues of certain proteins to form γ-carboxyglutamate residues, which can then bind calcium to activate these proteins. Within the realm of coagulation, vitamin K₁ activates factors II, VII, IX, and X and proteins C, S, and Z by oxidative carboxylation in the liver.² ⁵⁷ ⁶⁷ Activation of these coagulation factors is essential for hemostasis and normal functioning of the coagulation cascade. Variables contributing to the development of vitamin K₁ deficiency include inadequate diet; malabsorption; hepatic dysfunction, antibiotic therapy, which alters the GI flora; lack of vitamin K₁ supplementation; major surgery; and the use of warfarin.⁶⁷ Critically ill patients, who may have many of these variables,⁶⁷ are at high risk of developing coagulopathy associated with vitamin K₁ deficiency.² Re-ports indicate that as many as 51% of hospitalized patients have vitamin K₁ deficiency,¹⁰ ¹¹ with 34% resulting in hemorrhage and 24% associated with mortality.⁶⁷

Vitamin K₁ is commonly administered to patients with coagulopathies thought to be from vitamin K₁ deficiency and/or hepatic dysfunction.² ⁵⁷ It may be administered enterally, subcutaneously, or intravenously. Although either the enteral or the intravenous route of administration is recommended for urgent coagulopathy reversal, a recent study found that intravenous administration lowers INR quicker.² If given intravenously, the rate of administration should not exceed 1 mg/minute to avoid immunoglobulin E–mediated anaphylactoid reactions that are associated with the solubilizing vehicle. For patients with an elevated INR because of warfarin, the American College of Chest Physicians recommends oral vitamin K for an INR greater than 10 and no signs of bleeding and intravenous vitamin K 5–10 mg for all major hemorrhage regardless of the INR.⁶⁸ Cumulative intravenous doses of 20–30 mg are required to lower the INR from other causes of vitamin K.
deficiency; however, the efficacy of vitamin K is unpredictable, especially in the more severely ill and those with hepatic dysfunction. The half-life of vitamin K is 1.5–3 hours, and its full effect is achieved only after 6–12 hours. Therefore, vitamin K’s activity is slow, but the duration of action may last several days, irrespective of the route of administration. It is inexpensive and readily available.

**Fresh Frozen Plasma**

Fresh frozen plasma is derived from donated blood that has been centrifuged and separated from the cellular components.²,56,57 Each
A 250- to 300-mL unit contains soluble clotting factors and inhibitors, 1–2.5 mg/mL of fibrinogen, complement, albumin, and proteins C and S. Once frozen, plasma is kept at -18°C and can be stored for 12 months. After thawing, it must be kept at 1°C–6°C, labeled as “thawed plasma,” and transfused within 4 days. The process of freezing and thawing may affect the temperature labile clotting factors. The low and varying amounts of fibrinogen in FFP means that large volumes are often required to reverse coagulopathy; a dose of 15 mL/kg restores clotting factor levels to 30% of normal, and doses exceeding 30 mL/kg are required to increase fibrinogen concentrations. A target INR of less than 1.5 may never be reached by solely administering FFP because the fibrinogen concentration of FFP is below the target fibrinogen concentration required to fully reverse the coagulopathy. Normalization of the INR occurs in only 0.8% of patients, and a dose-response effect is inconsistent. The need for large doses, however, heightens the risk of fluid overload that may contribute to ongoing hemorrhage, cerebral edema, portal hypertension in the presence of liver dysfunction, and TACO, which occurs in 6% of patients receiving FFP. Hypervolemia leading to edema is of particular concern in patients with preexisting renal, cardiac, and pulmonary disorders. Plasma is also associated with TRALI at estimated rates of 1 in 5–10,000 units, a risk exceeding that of PRBC transfusions. Transfusion-related immunomodulation is also associated with FFP at occurrence rates exceeding RBC transfusions. Another concern is that extensive preparation time is required before FFP is ready to administer. After determining appropriate compatibility with the recipient, FFP must be thawed, which can take 30–60 minutes to process. Clinically, it is often difficult to estimate the number of FFP units that should be thawed for a given situation. Some centers ensure they have a constant supply of thawed or never-frozen plasma that is universally compatible; however, this can lead to units being wasted and may not be cytomegalovirus safe. Like other procoagulants, FFP is associated with thromboembolic adverse effects. The cost per unit of FFP is $70–$350.

</table>
Despite the aforementioned concerns, the use of FFP increased 23% between 2005 and 2012. Clinically applicable indications for FFP include replacement of an inherited single coagulation factor for which a virus-safe fractionated product does not exist, replacement of a specific protein deficiency such as C-1 esterase inhibitor, replacement of many coagulation factor deficiencies (DIC, hemorrhage), replacement of removed plasma during plasmapheresis in cases of thrombotic thrombocytopenic purpura, reversal of warfarin-associated hemorrhage, prevention of dilutional coagulopathy during hemorrhage, and prevention of bleeding in patients with advanced hepatic dysfunction and coagulopathy awaiting an invasive procedure or surgery. The most common reason to administer FFP in the United States is to prevent hemorrhage in patients with prolonged coagulation tests awaiting an invasive procedure. Limited data support this indication because a prophylactic dose of 12 mL/kg lowered the INR to less than 1.5 in only 54% of patients and did not lower the rate of bleeding after various invasive procedures compared with placebo. Moreover, clinically relevant bleeding problems in patients with hepatic dysfunction may be precipitated by increased venous pressures that may be associated with the large volume of fluid that accompanies FFP administration. Rather than trying to shorten clotting times, a conservative approach to plasma therapy in these patients using clinical judgment may prove beneficial. Fresh frozen plasma’s duration of action is typically 6–12 hours.

**Prothrombin Complex Concentrates**

Prothrombin complex concentrates are an inactive concentrate of variable, yet balanced, amounts of the vitamin K–dependent clotting factors. The concentration of vitamin K–dependent clotting factors in PCCs is about 25-fold higher than in plasma, and usual doses are equivalent to about 2 L of FFP. Prothrombin complex concentrates are
purified from pooled human plasma and lyophilized, which allows them to be reconstituted, as opposed to frozen and thawed. This provides significant advantages over FFP, including rapid administration, avoidance of compatibility testing, and the absence of risk of TRALI and TRIM. Like allogenic blood products, however, PCCs carry the potential risk of transmitting infectious microbes. Prothrombin complex concentrates contain factors II, IX, and X and are available with low amounts of factor VII (three-factor PCCs) and higher concentrations of factor VII (four-factor PCCs). Unlike three-factor PCCs, four-factor PCCs also contains albumin, proteins C and S, antithrombin, and heparin. Although the inclusion of anticoagulants theoretically reduces the occurrence of thromboembolic events that are associated with rapid induction of coagulation, they need to be considered in patients with known sensitivities to them (e.g., heparin-induced thrombocytopenia). The weighted mean average of thrombotic events with PCCs through 2008 was 2.3%, with higher rates associated with larger and repeated doses. A lower rate of 0.9% was identified in a review of eight clinical trials, although all of these studies included patients requiring warfarin reversal. Because of their rapid effect at reversing coagulopathy, PCCs may slightly increase the risk of thromboembolic events compared with FFP. Prothrombin complex concentrates are derived from human plasma, so patients declining blood products should be consulted before PCCs are administered. Dosage regimens of PCCs typically involve the administration of 50–200 mL of total fluid, so TACO and other manifestations of fluid overload are unlikely to occur. The acquisition costs of PCCs vary but are about $1.30 per unit with typical doses exceeding 2,000 units, and it is common practice to round to the nearest vial size. Prothrombin complex concentrates are available as a kit that contains the lyophilized powder and a provided diluent that is commonly mixed at the bedside but must be administered within 4 hours of reconstitution. Institutional procurement, storage, and distribution may originate from the blood bank rather than the pharmacy department.

In the United States, three-factor PCCs are only indicated for the
prevention and control of bleeding in patients with factor IX deficiency caused by hemophilia B. In contrast, four-factor PCCs are labeled for rapid reversal of acquired coagulation deficiency induced by warfarin in adult patients with acute major bleeding or the need for urgent surgery or an invasive procedure. The general consensus of several guidelines that have been published regarding the use of PCCs to reverse anticoagulation indicates that four-factor PCCs are the preferred therapy, FFP may be needed if three-factor PCCs are used, and FFP is likely not needed if four-factor PCCs are used. One guideline suggests that rFVIIa can be considered in addition to three-factor PCCs when emergency reversal is required. The results of studies comparing four-factor PCCs with FFP in patients receiving anticoagulation with vitamin K antagonists show that four-factor PCCs reverse INR more rapidly with less fluid administration and achieve greater rates of effective hemostasis. The dosage regimens are based on units of factor IX, but an adjustment for four-factor PCCs includes the INR (INR of 2–4 = 25 units/kg, INR of 4–6 = 35 units/kg, INR of greater than 6 = 50 units/kg). This latter adjustment for the INR is often applied to dosage regimens of all products when they are used in clinical scenarios of prolonged clotting in the absence of anticoagulation. In a retrospective assessment of patients with coagulopathy caused by trauma, adding PCCs to FFP accelerated INR reversal, reduced the number of units of PRBCs and FFP administered, lessened the total costs associated with procoagulant administration, and lowered mortality. Although not systematically studied for the prevention of bleeding in patients with coagulopathies owing to causes other than anticoagulation and awaiting surgery or an invasive procedure, PCCs likely reverse INR more rapidly than does FFP with substantially less fluid and may expedite the time to the intervention. The duration of action depends on the dose of PCC administered but is typically 12–24 hours.

Activated PCC or factor VIII inhibitor bypassing complex (FEIBA; Baxter Healthcare, Westlake Village, CA) is an anti-inhibitor coagulation complex used in the management of hemorrhage in patients with hemophilia and acquired factor VIII inhibitors. It is composed of
factors II, IX, and X; small amounts of activated factor VII; and factor VIII antigen. It acts by facilitating thrombin generation on the surface of activated platelets and activating factor X. It is not commonly used to manage or prevent hemorrhage in patients without factor VIII inhibitors, but case reports show it may successfully reverse new oral anticoagulant agents.\textsuperscript{61} It is associated with thrombosis and the propagation of DIC, and it may pose a risk of transmitting infectious microbes because it is manufactured from human blood pools.

**Recombinant Activated Factor VII**

Recombinant activated factor VII is indicated for the treatment and prevention of bleeding in patients with hemophilia with inhibitors, cases of factor VII deficiency, and individuals with Glanzmann thrombasthenia with little to no response to platelets.\textsuperscript{57} Recombinant activated factor VII stimulates the extrinsic pathway by interacting with exposed endothelial tissue factor to activate factors IX and X. At pharmacologic doses, rFVIIa bypasses the need for tissue factor by generating thrombin on the surface of activated platelets that are localized to the site of injury.\textsuperscript{67} Both mechanisms ultimately produce activated factor X, which drives thrombin burst to cleave fibrinogen to fibrin. Factor VII levels are often extremely low in patients with major hemorrhage. To optimize the activity of rFVIIa, patients should be normothermic with an arterial pH greater than 7.20.\textsuperscript{67,72} Results from studies using dosage regimens of 10–90 mcg/kg are mixed with respect to reducing hemorrhage expansion and limiting the administration of other procoagulant products and/or PRBCs in bleeding cases associated with vitamin K antagonists, liver disease, liver transplant, trauma- and surgery-associated coagulopathy, cardiothoracic surgery, and spontaneous intracranial hemorrhage.\textsuperscript{57,72} None of these studies, however, has shown clinical benefits of morbidity or mortality.\textsuperscript{57} Recombinant activated factor VII reduces prolonged clotting times within 15–30 minutes of administration and typically lasts 2–6 hours. Reversal time is faster than that of PCCs and FFP, but duration may be shorter. Several studies comparing rFVIIa with FFP show that rFVIIa may expedite invasive procedures or surgery in patients with
coagulopathies from causes other than anticoagulants. These nonproprietary indications represent more than 95% of rFVIIa use in the United States.\textsuperscript{57,72} Some have recommended against the use of rFVIIa in favor of PCCs for INR reversal, regardless of the etiology of prolonged clotting, because rFVIIa may not adequately restore thrombin generation over time to the same extent as other products, resulting in a duration of action that is substantially shorter.\textsuperscript{2,57} The rate of thromboembolic events associated with rFVIIa administration is 11.1\% across studies, but only the rate of arterial events exceeds that of placebo (5.5\% vs. 3.2\%, p<0.003).\textsuperscript{72-74} The occurrence of thromboembolic events increases with patient age and rFVIIa dose. Recombinant activated factor VII contains no human elements and may be administered to patients not accepting products derived from human sources. The cost of rFVIIa is around $1,800 per milligram, and it is common practice to round to the nearest milli-gram.\textsuperscript{57} Institutional procurement, storage, and distribution may originate from the blood bank rather than the pharmacy department. As with PCCs, rFVIIa is available as a lyophilized powder in a kit with a syringe that contains a histidine diluent, and it must be administered within 3 hours of reconstitution.

**Platelet Optimization**

The activity of platelets may be improved by increasing the platelet count through administering platelets or enhancing their functionality using desmopressin or estrogen.

**Platelets**

Platelets are essential for primary hemostasis because they form a plug at the site of endothelial injury. Circulating platelets are activated by exposed collagen when the integrity of the endothelial lining is compromised. Signaling molecules (vWF, fibrinogen, platelet-derived growth factor, ADP, serotonin) lead to conformational changes in platelets, specifically of the GPIIb/IIIa receptors on the surface.\textsuperscript{1} Endothelial release of vWF also decelerates platelets at sites of high
shear stress (rapid blood flow though narrow blood vessels) and enhances platelet adhesiveness. Further platelet recruitment occurs as activated platelets secrete thromboxane A\(_2\) and ADP, and the platelet phospholipid surfaces and calcium potentiate factors V, VIII, IX, and X. Activated platelets also bind to circulating fibrinogen, which forms and stabilizes local platelet aggregates to form plugs.

Bleeding risk is minimal when platelet counts exceed 50 × 10\(^9\)/L but increases dramatically when counts drop below 10 × 10\(^9\)/L. These data, however, are derived mostly from patients with bone marrow failure and compromised thrombopoiesis, so application to critically ill patients is indeterminate. A consensus regarding the optimal platelet count to prevent bleeding or maintain during hemorrhage has not been well established. In general, platelet counts of 20 × 10\(^9\)/L or greater is used as a minimum threshold to prevent bleeding and 30–50 × 10\(^9\)/L or greater is targeted during hemorrhage, respectively. Higher thresholds of 100 × 10\(^9\)/L may be warranted in some patient-specific scenarios such as neurosurgery or orthopedic surgery. In addition, platelet dysfunction may occur because of issues other than low platelet counts (e.g., low vWF, IIb/IIIa inhibition).

Platelets are separated from RBCs and concentrated by repeated centrifugation. Platelets are stored at 22°C for up to 8 days but require constant agitation. Bacterial contamination increases and the efficacy of transfusion decreases after 5 days of storage. Compatibility testing is performed before platelets are administered. Each platelet transfusion is dosed in “six-packs,” with each containing 6 units of platelets from several donors or a single apheresis unit. A 6-unit transfusion should raise the platelet count by 25–50 × 10\(^9\)/L and last up to 72 hours. Refractoriness, defined by a platelet rise less than 5 × 10\(^9\)/L within 1 hour of transfusion, indicates the presence of alloimmunization or platelet antibodies (e.g., heparin-induced thrombocytopenia, idiopathic thrombocytopenic purpura), and additional administration of platelets may heighten the immune response and further aggregate platelet destruction. The rate of alloimmunization is less than 1%, but as many as 70% of patients receiving several RBC or platelet transfusions may temporarily develop alloantibodies.
use of leukoreduced blood products delays or prevents this phenomenon.

As with PRBCs and FFP, platelets are high-volume products and share many of the same risks, including TRALI, TRIM, TACO, acute hemolysis, and anaphylaxis. A concern unique to platelets is transfusion-related sepsis with bacterial contamination of stored platelets at room temperature. Platelet administration is also associated with thrombotic complications. Each 6-unit transfusion is estimated to cost $350–$500.

Enhancing Platelet Function

Desmopressin is a synthetic analog of endogenous human antidiuretic hormone. Traditionally, it was used to treat inherited bleeding disorders such as vWF deficiency and mild forms of factor VIII deficiency hemophilia A. Desmopressin causes the release of vWF, factor VIII, and tissue plasminogen activator from the endothelium, increasing their plasma concentrations by 2- to 20-fold within 30 minutes of an intravenous dose of 0.3 mcg/kg. von Willebrand factor acts as a carrier protein binding to factor VIII and promotes platelet adhesion at sites of endothelial injury. The duration of action is about 4 hours. Desmopressin may be particularly useful if platelet dysfunction is caused by aspirin or dipyridamole. It has been shown to shorten bleeding time in patients with uremia and reduce blood loss during hemorrhage. Repeated doses for short periods should be avoided because this may facilitate fibrinolysis by stimulating the release of plasminogen activator from the endothelium.

High doses of intravenous estrogen also enhance platelet function by increasing factors VII, VIII, IX, X, and prothrombin. It also reduces antithrombin and protein S. The slow onset of action limits the practicality of estrogen for promoting hemostasis, but it may be tried in refractory cases of presumed platelet dysfunction.

Inhibiting Fibrinolysis
Fibrinogen is a required protein for hemostasis. Produced in the liver, it circulates at the highest concentration of all clotting proteins. It is the physiologic substrate of thrombin, activated factor VIII, and plasmin. Activated thrombin cleaves fibrinogen and catalyzes fibrin polymerization to form a structural network that is the basis of each clot. Cross-linking of fibrin polymers is induced by factor VIIIa and increases the elasticity of clots to enhance resistance to fibrinolysis. Fibrinogen also serves as a ligand for GPIIb/IIIa receptors on platelets to enhance platelet adhesion.

**Fibrinogen**

Although the half-life of fibrinogen is about 3.8 days, fibrinogen catabolism exceeds synthesis during major hemorrhage, especially in cases of liver dysfunction. Ongoing hemorrhage and dilutional coagulopathy can cause fibrinogen concentrations to decline, and it is often the first factor to be relatively depleted during uncontrolled bleeding. Low concentrations are an independent risk factor for bleeding during surgery. Despite little supporting evidence, several guidelines recommend maintaining fibrinogen concentrations of 80–100 mg/dL. Higher target thresholds may be required to optimize hemostasis because clot strength increases linearly with fibrinogen concentration, even up to 1,000 mg/dL. Hypofibrinogenemia will prolong clotting assays.

Fibrinogen is available from three sources: FFP, cryoprecipitate, and factor concentrate. The amount of fibrinogen in FFP is minimal, and the dosing requirements to achieve adequate fibrinogen concentrations are usually limited by the fluid volume of FFP. Each unit of cryoprecipitate is prepared from the centrifugation of 1 unit of FFP using a method that precipitates high-molecular-weight proteins such as factor VIII, vWF, and fibrinogen. The insoluble precipitate is reconstituted in 20–40 mL of plasma as cryo-precipitate and stored at -18°C for up to 12 months. The amount of fibrinogen in cryoprecipitate varies substantially but is about 1,500 mg/dL. Each unit should increase fibrinogen concentrations by 5–10 mg/dL. It also
contains factor VIII (80 IU or greater), factor XIII VIII (30% of original plasma content), vWF (about 50% of original plasma content), and fibronectin.\textsuperscript{62} It is considered to be leuko-reduced without additional filtration and does not require antibody screening. Like other blood products, cryoprecipitate requires ABO compatibility testing, and it is associated with TRALI, TRIM, and thrombosis but is less likely to cause TACO or hypervolemia.\textsuperscript{62} Fibrinogen concentrate is manufactured from plasma and commercially available as a pasteurized lyophilized powder that is virus free. Currently, only one product (RiaSTAP; CSL Behring, King of Prussia, PA) is available in the United States, and it is indicated for the treatment of acute bleeding episodes in patients with conditions of hypofibrinogenemia.\textsuperscript{62} It is reconstituted in sterile water to a final vial concentration of 20 g/L and contains 900–1300 mg of fibrinogen per vial.\textsuperscript{62} It also contains human albumin. Although not recommended by the manufacturer, it may be infused over seconds to minutes to rapidly replete fibrinogen. Unlike cryoprecipitate, it does not require ABO compatibility testing and is not associated with TRALI or TRIM, but unfounded concerns exist that the concentrate may increase thrombotic events. The costs of each product must consider that the procurement of cryoprecipitate also produces PRBCs and cryosupernatant, but the concentrate does not require thawing and compatibility testing and is not associated with TRALI and TRIM.

**Antifibrinolysis**

The blood products and pharmacologic agents discussed to this point enhance coagulation and/or improve clot stability. Antifibrinolytic agents inhibit the enzymatic degradation of clot. Antifibrinolytic agents currently in use are the synthetic lysine analogs ε-aminocaproic acid and tranexamic acid.\textsuperscript{2} These agents reversibly bind to the ly-sine-binding site of the fibrin clot to competitively inhibit the binding of plasminogen to fibrin at the same lysine-binding site. This prevents the conversion of plasminogen to plasmin and subsequent plasmin-mediated fibrinolysis. The antifibrinolytic activity of tranexamic acid in vitro is about 10-fold
higher than that of ε-aminocaproic acid.\textsuperscript{2} Most centers use tranexamic acid because it is slightly less expensive with acquisition costs of $50–$70 per 1,000-mg vial or $250–$500 for most therapeutic dosage regimens. Both agents are associated with thrombosis, and rapid administration of tranexamic acid may cause hypotension.

**SPECIFIC PATIENT POPULATIONS**

Hemostatic management varies by the etiology causing coagulopathy or thrombocytopenia. This section will review preventive strategies and management options of hemorrhage in specific patient populations.

**Perioperative/Surgical Bleeding**

Historically, management of perioperative bleeding was reactive and focused on restitution of intravascular volume with blood products at the time of hemorrhage. Today, greater attention is given to preventing blood loss from the outset because few data show a favorable benefit-risk ratio related to blood product administration.\textsuperscript{21,38,41} Bleeding and transfusions independently increase morbidity and mortality as well as increase costs. These latter economic consequences relate to prolonged hospital length of stay and operating room time, greater laboratory testing, and the costs associated with blood products. Blood management programs aimed at minimizing the use of blood products in surgical patients improve patient outcomes and resource use. Some centers offer “blood-free” operating rooms as a result of practice initiatives that minimize bleeding risks preoperatively and limit blood loss intraoperatively.

The process of minimizing allogeneic blood products begins with preoperative identification of surgical patients at high risk of bleeding through completion of a structured history.\textsuperscript{39,41,75} This history should include clinical conditions (e.g., renal disease, liver disease) associated with bleeding as well as family bleeding history (e.g., hemophilia, factor deficiencies). Advanced age increases the risk of hemorrhage. In addition, liver, spine, craniofacial, cardiopulmonary, and major
urological surgical procedures are prone to bleeding. Two modifiable factors that may be targeted in these patients are managing preoperative anemia and reversing preexisting coagulopathy. Strategies used to increase RBC mass in elective surgery patients include iron replacement therapy when iron-deficient anemia is present, the administration of erythropoiesis-stimulating agents (epoetin alfa or darbepoetin alfa) when iron deficiency has been ruled out, and autologous blood donation. All three strategies require planning weeks before surgery and implementation at least several days before the procedure. Managing preexisting coagulopathy includes the discontinuation and/or reversal of systemic anticoagulants preoperatively. This includes heparin, low-molecular-weight heparins, antiplatelet agents, and oral anticoagulants such as warfarin or the new agents. These latter agents are particularly challenging in emergency surgery cases because pharmacologic reversal agents are unpredictable or not yet available. Selected herbal agents with anticoagulant activity should also be discontinued preoperatively (e.g., garlic, ginseng, saw palmetto), as should any other pharmacologic agents that may increase bleeding (e.g., valproic acid, selective serotonin reuptake inhibitors). The timing of discontinuing these agents will depend on their pharmacologic half-lives and the potential lack of reversibility. Point-of-care testing for platelet function should aid in determining the appropriate time to discontinue antiplatelet therapies.

Intraoperative strategies aimed at reducing blood loss include patient positioning, operative technique and environment, regional anesthesia, ventilation, controlled hypotension, acute normovolemic hemodilution, RBC salvage or recovery, and the use of topical hemostats. Ideally, patients are positioned during surgery to reduce arterial pressure and maximize venous drainage away from the wound. Operative techniques vary, but blood loss is minimized using tourniquets, infiltrating the surgical site with local vasoconstrictors, and using advanced surgical techniques (e.g., laparoscopic, endoscopic, robotic, transcatheter). Regional anesthesia using central neuraxial blocks such as spinal/epidural anesthesia reduces blood loss by 25%–30% by inducing sympathetic blockade to
minimize perfusion of the surgical site and decreasing venous tone to enhance drainage. Ventilator settings that minimize positive end expiratory pressure and use low tidal volumes under general anesthesia decrease mean intrathoracic pressure to increase venous return and reduce blood loss. The environment refers to ensuring that laboratory values are normalized (e.g., pH, ionized calcium, fibrinogen) and that core body temperature is 35°C or greater. Controlled hypotension reduces arterial blood flow to the surgical site to minimize blood loss. During acute normovolemic hemodilution, several units of blood are collected from the patient preoperatively and replaced with crystalloid or colloid solutions so that blood loss during the procedure contains fewer RBCs. Collected blood is stored at the patient’s bedside during the surgery to minimize the administrative costs and is given back to the patient at a predefined transfusion trigger or the conclusion of surgery. Autologous blood cell salvage is the process of recovering the patient’s blood from the surgical field, washing and filtering, and reinfusing to the patient. Cell recovery is cost-effective when blood loss is expected to be high. In all cases, surgical procedures should use a restrictive hemoglobin transfusion trigger of 6–7 g/dL, which will also reduce blood transfusions. In addition, using extracorporeal systems with mini-circuits, minimizing phlebotomy, collecting samples in small-volume (pediatric) collection tubes, or using alternative sampling methods when possible (e.g., pulse oximetry rather than blood gas analyses) during and after surgery reduces blood loss. In general, phlebotomy should be minimized across all patients. Although surgical drains reduce hematoma expansion and compression of vital structures, they are associated with increased blood loss and enhanced transfusion rates of up to 40%. Reinfusion of the blood from wound drains is safe if the volume is less than 1 L and the process is completed within 6 hours.

Topical hemostats, surgical sealants, and adhesives are adjunctive approaches to control bleeding together with blood products, systemic agents, and direct approaches (e.g., pressure at bleeding site, suture ligation, hemoclips, electrocautery). They may also be used when the latter approaches are not feasible (e.g., surgical fields with diffuse
oozing). These agents are most commonly used in the operating room, although they can be used in other settings to augment hemostasis (e.g., uncontrollable epistaxis, dermal bleeds, or oral-pharyngeal hemorrhage). The ideal topical hemostat is one that is safe, provides prompt and reliable hemostasis, is easy to use, is simple to store and prepare, and is affordable. Although an ever-expanding number of these agents are commercially available, no agent meets all of these criteria. Inadvertent intravascular administration of these products is also a risk. Because many of the topical hemostats are considered devices rather than drugs, institutional procurement and distribution often originates from materials management rather than the pharmacy department.65

Topical hemostats are generally categorized into mechanical agents, biologically active agents, flowables, and fibrin sealants (Table 24.6). Mechanical hemostats provide a matrix on which blood clotting can occur as well as a bleeding barrier. The source materials for these physical matrices are gelatin, collagen, cellulose, and polysaccharide starches. These materials are supplied in a wide variety of forms including sponges, foams, sheets, and spheres. Biologically active hemostats all contain thrombin that has an integral enzymatic role in clot formation by stimulating the formation of fibrin from its precursor, fibrinogen. Three thrombin products are available in the United States and vary in their origin: bovine derived, human plasma derived, and recombinant human derived. The potential safety issue distinguishing these three products is the development of antibodies, depending on the thrombin source. Flowable hemostats are characterized by their consistency and gel-like properties rather than their mechanical counterparts. Limited clinical data suggest the superiority of at least one flowable agent to mechanical hemostats relative to the rates of hemostasis and shorter time to hemostasis in cardiothoracic surgery patients. As with the mechanical hemostats, flowable agents can be combined with thrombin to provide physical and active hemostasis. Fibrin sealants are unique because they combine human thrombin with human fibrinogen to promote clot formation. Unlike the active hemostats, they do not require patient-supplied fibrinogen at the active bleeding site to promote hemostasis. Surgical sealants and synthetic adhesives are used for hemostasis but have broader indications as well. Examples for surgical sealants include vascular...
reconstruction procedures, dural repairs during cranial surgery, and pleural repairs. In contrast, synthetic adhesives can be used to seal adjacent skin surfaces together and closure of skin incisions or lacerations. Sutures, however, are significantly better for minimizing surgical wound dehiscence.

As mentioned, several types of surgery are associated with major bleeding complications. Cardiac surgery, which has the most data for managing hemorrhage, will be discussed in detail. Of note, most surgeons are willing to accept a state of relative hypocoagulation, assuming the hemorrhage is not life threatening. Around 20% of patients undergoing cardiac surgery have perioperative hemostatic abnormalities, and 15% of all blood products in the United States are used in cases of cardiac surgery. In the 2%–6% of cardiac cases requiring surgical revision, coagulopathy is present in 53%, and an identifiable source of bleeding is found in only 67%. Reexploration is associated with a 3- to 4-fold increase in mortality. Acutely, hemorrhage may lead to shock, cardiac tamponade, and cardiac decompensation, and hemorrhage increases the likelihood of infection, arrhythmias, pulmonary complications, and other organ dysfunctions. These surgical patients often develop coagulopathies from many etiologies including iatrogenic anticoagulation to prevent catastrophic clot formation during extracorporeal circulation, DIC, dilutional, hypothermia, acidosis, and the use of anticoagulant or antiplatelet agents before surgery. In extracorporal circulation, blood contact with artificial surfaces and air bubbles simultaneously activates coagulation factors, especially factor VII, to further stimulate thrombin generation while enhancing fibrinolysis. Heparin is the primary anticoagulant used during extracorporeal circulation and is easily reversed with protamine; however, protamine can inhibit coagulation, paradoxically increasing the risk of hemorrhage.

Treatment goals for these patients are aimed at maximizing clot formation and stabilization by enhancing coagulation and reducing fibrinolysis, rapidly controlling hemorrhage, and reducing the likelihood of reexploration. These goals are applicable to hemorrhage associated with other types of surgery and trauma. An added level of
complexity is hemorrhage associated with surgery that involves grafting such as coronary artery bypass grafting or solid organ transplant because graft patency is vital and may limit administration of procoagulant and antifibrinolytic agents. Conventional therapies used to reverse coagulopathy and/or minimize the severity of hemorrhage during surgery include PRBCs, FFP, PCCs, platelets, cryoprecipitate, antifibrinolytics, desmopressin, and topical hemostatic agents (Table 24.6 and Table 24.8). In general, these agents are used to achieve or maintain the aforementioned laboratory goals for INR, platelet count, and fibrinogen concentrations and/or normal point-of-care viscoelastic hemostatic parameters (Table 24.9; Figure 24.2) (see Traumatic Injury section for more detail). A meta-analysis of tranexamic acid use in surgery across 104 trials and 8,030 subjects found that it reduced blood loss by 34% (OR 0.66; 95% CI, 0.65–0.67; p<0.001) consistently across all types of surgery (cardiac, orthopedic, head and neck, obstetrical and gynecologic, urological, and hepatic), irrespective of whether it was administered pre- or post-incision, and without increasing thromboembolic events. Recombinant activated factor VII is a controversial therapy because results of studies of surgical patients are mixed with respect to the amount of blood loss, transfusion requirements, or hemorrhage control. No study has shown improved morbidity or mortality with rFVIIa when applied to surgical patients. None of the aforementioned therapies, however, should supplant rapid surgical intervention.

**Traumatic Injury**

Hemorrhagic shock is most commonly seen after acute injury. However, non-trauma cases of massive hemorrhage include patients with GI bleeding, obstetrical patients, and surgical procedures with the potential for massive bleeding complications. The overarching goal in hemorrhagic shock is improving patient outcomes through source control, restoration of adequate end-organ perfusion, increased oxygen-carrying capacity of the circulating blood, and reversal of the hypocoagulable state often accompanying massive blood loss. As with surgery, coagulopathy from trauma is the consequence of many factors including hypothermia, acidosis, DIC, and dilution.\(^{75,81}\) About 9% of patients with trauma present with hypothermia, and about 65% of hypothermia can be attributed to radiant heat loss from removal of clothing, muscle relaxation, frequent removal of blankets for examinations, or resuscitation with cold intravenous fluids.\(^{12,40}\) Unlike elective surgery where normovolemic hemodilution conserves blood,
excessive resuscitation during trauma with crystalloid fluids dilutes clotting factors, increases hydrostatic pressure, and reduces quality clot formation.

Acute coagulopathy of trauma is recognized as a distinct entity as patients progress from an early hypocoagulable/profibrinolytic phase to a prothrombotic phase.\textsuperscript{12,81,82} The defining etiology is traumatic shock leading to systemic hypoperfusion, which slows the clearance of thrombin.\textsuperscript{81,82} Enhanced binding of thrombin to endothelial thrombomodulin activates protein C, inactivates factors Va and VIIIa, and abrogates plasminogen activator inhibitor and thrombin activatable plasminogen inhibitor to produce greater fibrinolysis. Tissue hypoperfusion generates new expression of thrombomodulin, furthering the hypocoagulable state. In contrast, massive tissue destruction also releases damage-associated molecular pattern molecules such as histones and mitochondrial DNA, which lead to micro-vascular thrombosis by inducing platelet activation, promoting thrombin generation, and impairing protein C activation. Tissue injury also releases the proinflammatory cytokines, IL-1\textsuperscript{β} and tumor necrosis factor α, which elicit tissue factor expression on the surface of monocytes and endothelium to propagate thrombosis and possibly incite DIC. Traumatic brain injury also causes the release of tissue factor from injured neurons.\textsuperscript{81,82}

The reversal of coagulopathy with blood products and pharmacologic agents is critical because coagulopathy is an independent risk factor for morbidity and mortality in trauma patients with hemorrhagic shock (Table 24.8).\textsuperscript{39,40} Massive transfusion protocols were developed in an effort to minimize RBC transfusions and crystalloids in trauma patients with hemorrhagic shock (Figure 24.3).\textsuperscript{12,38,40} Increasing the speed and efficiency of transfusions are other potential benefits of MTPs. Massive transfusion protocols are processes for administering RBCs, plasma, and platelets in a set ratio, as well as hemostatic agents in a standardized manner versus guiding blood product administration on the basis of laboratory data.\textsuperscript{83-87} These protocols are often initiated by an order set or telephone call to the blood bank, and the blood products are delivered to the bedside
ready to use. The first MTP used a ratio of 1:1:1 (PRBC/plasma/platelets) for civilian trauma patients and was based on military data.\textsuperscript{12,38} Massive trans-fusion protocols are physiologically rational because whole blood has an RBC/plasma ratio of 1:1.\textsuperscript{12,38} Although studies are almost uniformly positive, most were observational and usually based on before-after methodology at single centers.\textsuperscript{12,38} The Prospective, Observational, Multicenter, Major Trauma Transfusion (PROMMTT) study was conducted across 10 U.S. level 1 trauma centers and evaluated 1,245 patients who received at least 1 PRBC unit within 6 hours of admission.\textsuperscript{88} Findings from the PROMMTT study indicate that ratios of RBC to FFP of 1:1 or less and ratios of RBC to platelets less than 1:2 within 6 hours of admission were independently associated with decreased 30-day mortality rates. A follow-up study examining the optimal PRBC/FFP/platelet ratios, known as the Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) study, randomized 680 hemorrhaging patients to PRBC/plasma/platelets in ratios of 1:1:1 to 2:1:1.\textsuperscript{89} The results showed similar mortality rates between groups at 24 hours and 30 days despite fewer deaths from exsanguination within 24 hours (9.2\% vs. 14.6\%, \( p=0.03 \)) and greater achievement of hemostasis in the 1:1:1 group (86\% vs. 78\%, \( p=0.006 \)). Most trauma centers have an MTP in place, but significant variability exists relative to the fixed ratio of blood products within the protocol. An average of 10 MTP studies of more than 4,000 trauma patients showed a mean RBC/plasma ratio of less than 3:2 and an RBC/platelet ratio less than 2:1.\textsuperscript{86,87}
Figure 24.2 Schematic diagram of thromboelastogram showing reaction time (r), clot formation time (K), alpha (α) angle, maximum amplitude (MA), and maximum amplitude (A₆₀).

Compared with a normal trace (A), fibrinolysis (B) is associated with prolonged r and K times, reduced MA and A₆₀, greater LY₃₀, and possibly obtuse α angle; hypercoagulation (C) is associated with shorter r and K times, heightened MA and A₆₀, relatively normal LY₃₀, and acute α angle; hypocoagulation (D) is associated with lengthened r and K times, reduced MA and A₆₀, relatively normal LY₃₀, and obtuse α angle.²⁷,⁷⁷,⁷⁸
A significant limitation of studies examining MTPs is survival bias. Plasma must be thawed before administration, so patients bleeding profusely may die after receiving PRBCs but before receiving FFP. In addition, administering platelet transfusions in trauma patients without thrombocytopenia is questionable, and the “shotgun” approach may result in over-replacement of products with limited supply and contribute to adverse events and/or the propagation of DIC. In many cases, systemic pharmacologic agents or factor-specific products are included in these MTPs. Consideration of other blood products for inclusion in MTPs such as PCCs, cryoprecipitate, and fibrinogen concentrates may also be directed by this strategy. Massive transfusion protocols are often applied to etiologies of hemorrhage other than trauma.
There is a trend toward using a hybrid, more individualized approach to treating patients, which combines visco-elastic testing data and a structured MTP. Thromboelastography (TEG) or rotational TEG (ROTEG) is an integral element of this point-of-care management approach. The primary advantage of these tests over other conventional tests used during surgery and trauma is that they offer delineated assessments of coagulation, clot stability, and fibrinolysis (Table 24.9; Figure 24.2). Disadvantages of the TEG or ROTEG include cost, differences in results, and time to obtain results on the basis of technique and device. Several reports suggest that viscoelastic testing used during surgery or trauma to specifically direct the appropriate use of therapies improves coagulation, minimizes fibrinolysis, and limits patient exposure to unnecessary blood products. Used in this way, these tests can facilitate the efficient use of blood products and hemostatic agents while reducing blood loss and potentially improving clinical outcomes. Of note, these viscoelastic hemostatic assays are commonly used during non-trauma surgical procedures to monitor coagulation and guide therapies and are becoming more commonly applied across ICUs in nonsurgical types of hemorrhage.

Tranexamic acid and rFVIIa are two pharmacologic products that have been systematically studied in trauma patients at high risk of hemorrhage. The Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage (CRASH)-2 trial was a multicenter study of
274 hospitals in 40 countries that randomized 20,211 adult trauma patients actively hemorrhaging or at high risk of hemorrhage and within 8 hours of injury to tranexamic acid (loading dose 1 g over 10 minutes; then infusion of 1 g over 8 hours) or matching placebo. All-cause 28-day hospital mortality, the primary outcome, was lower with tranexamic acid (14.5% vs. 16%; RR 0.91; 95% CI, 0.85–0.97, p=0.0035). The risk of death caused by bleeding was also lower (4.9% vs. 5.7%; RR 0.85; 95% CI, 0.76–0.96, p=0.0077). The greatest survival benefit was most evident for the day of injury and when treatment was initiated within 3 hours of injury. Exploratory analyses of the CRASH-2 trial found that treatment given after 3 hours increased the risk of death caused by bleeding (4.4% vs. 3.1%; RR 1.44; 95% CI, 1.12–1.84, p=0.004). The contrasting survival benefit, given the timing of administration, may pertain to the pathophysiology of coagulopathy from acute trauma because early administration may help control the hypocoagulable/profibrinolytic phase seen shortly after trauma. Vascular occlusive events (1.7% vs. 2%; RR 0.84; 95% CI, 0.68–1.02, p=0.084) and the use of blood products were similar between groups. Cost-effectiveness analyses show that the incremental cost of using tranexamic acid per life-year gained is less than $100, especially when administered within 3 hours of injury. Because of these results, most trauma centers administer tranexamic acid when patients present within 3 hours of injury. Considerable controversy exists about the administration beyond 3 hours.

Before tranexamic acid was studied, rFVIIa was evaluated in 301 bleeding patients with blunt or penetrating trauma across 32 hospitals. Patients requiring 6 units of PRBCs within 4 hours of injury were randomized to receive rFVIIa 200 mcg/kg, followed by two doses of 100 mcg/kg 1 and 3 hours after the first dose or placebo. In blunt trauma, rFVIIa reduced RBC transfusions within 48 hours (2.6 units, p=0.02), the primary outcome, and the need for massive transfusion, as defined by greater than 20 PRBC units (14% vs. 33%, p=0.03). The rate of acute respiratory distress syndrome was also decreased (29% vs. 42%, p=0.03). These results were not statistically different for the penetrating trauma group. Mortality and thromboembolic rates
were similar between groups. A subgroup analysis showed that the greatest benefit occurred when coagulopathy was present.\textsuperscript{97} A phase III study of patients who bled 4–8 RBC units within 12 hours of injury and were still bleeding despite resuscitation and operative management using a similar dosing scheme was terminated early after 573 patients (481 with blunt trauma) of 1,502 planned subjects because mortality rates (11\% vs. 10.7\%, respectively) were lower than anticipated, resulting in futility concerns.\textsuperscript{98,99} Similar to the previous study, blunt trauma patients randomized to rFVIIa received fewer PRBC units (7.8 ± 10.6 vs. 9.1 ± 11.3, p=0.04) and total units of allogenic blood products (19 ± 27.1 vs. 23.5 ± 28, p=0.04). Thromboembolic rates were similar between groups. Because of the cost of rFVIIa and the newer data with tranexamic acid, most trauma centers reserve rFVIIa use for patients with refractory hemorrhage and often use dosage regimens of 40–90 mcg/kg rather than the cumulative dose of 400 mcg/kg that was studied.

Management and Prevention of Bleeding in Patients with Cirrhosis

The complex nature of the coagulation system in patients with hepatic insufficiency makes management difficult and often controversial. Traditionally, clinicians associated hepatic insufficiency with an anticoagulated state and increased bleeding tendency, so management was targeted at reversing coagulation tests such as PT/INR.\textsuperscript{26-28} However, recent literature suggests that patients with hepatic insufficiency have a balanced coagulation system and that prolonged coagulation tests do not correlate with bleeding risk.\textsuperscript{26-28} The focused use of blood products in clinical scenarios is currently the mainstay of therapy for these patients, in addition to the potential use of vitamin K, rFVIIa, and PCCs.\textsuperscript{7,27,28} Concomitant renal dysfunction is common in patients with hepatic insufficiency and hemorrhage, so desmopressin may be administered if uremia is present in an effort to improve platelet function.\textsuperscript{7,28}

Despite the lack of literature proving their efficacy, blood products
(FFP, platelets, and cryoprecipitate) are commonly administered in patients with hepatic insufficiency to control active bleeding or reverse PT/INR before invasive procedures. Fresh frozen plasma may partly reverse prolonged values of PT/INR; however, achievement of an INR less than 1.5 occurs in fewer than 10% of cases. Similarly, correlation between a corrected PT/INR and clinically significant bleeding cessation or occurrence in the case of prophylactic administration has not been established in this patient population. The amount of plasma needed to consistently reduce the PT/INR is often 10–15 mL/kg, which exposes these patients to increased volume expansion and subsequent risks of TACO, TRALI, and cerebral edema and worsening portal pressure to promote ongoing hemorrhage. In addition, the effects of FFP are short lived, which is consistent with the short half-life of factor VII. The lack of clinical evidence and the risks associated with the administration of FFP in this patient population argue against its routine use; however, many clinicians are compelled to try to reverse the coagulopathy in cases of hemorrhage and to prevent bleeding.

Administration of cryoprecipitate may aid in restoring “normal” concentrations of fibrinogen in patients with hepatic insufficiency who may have lower concentrations of fibrinogen and impaired aggregation of fibrin monomers. The exact target concentration of fibrinogen has not been established, and systemic fibrinogen concentrations may not give an accurate assessment of bleeding risk, given the uncertainty regarding the degree of dysfibrinogenemia found in patients with hepatic insufficiency. However, in clinical practice, doses of cryoprecipitate are typically titrated to achieve a fibrinogen concentration of 100–120 mg/dL in the setting of bleeding, and they typically range from 1 to 2 units/kg of body weight. Caution should be taken during administration because cryoprecipitate lacks certain clotting factors and can worsen the already imbalanced coagulation system seen in patients with hepatic insufficiency.

The quantity and quality of platelets is also important to achieve primary hemostasis, and patients with hepatic insufficiency often have abnormalities in their platelet production and function. Transfusions
of platelets typically result in an immediate rise in platelet counts; however, the target platelet concentration in this patient population remains poorly defined. In-vitro studies have shown that platelet counts of $50 \times 10^9/L$ or greater enable adequate thrombin generation, whereas concentrations of $100 \times 10^9/L$ or greater may enable optimal thrombin generation. In clinical practice, it is reasonable to aim for platelet counts of $50 \times 10^9/L$ or greater in the setting of active bleeding or of $20 \times 10^9/L$ or greater to prevent hemorrhage in high-risk procedures.\textsuperscript{26,28,34,35}

Vitamin K deficiency is a common complication of hepatic insufficiency and may occur because of malnutrition and malabsorption. In addition, vitamin K–dependent clotting factors (II, VII, IX, and X) are synthesized in the liver and are often deficient in patients with hepatic insufficiency.\textsuperscript{11,37} Prothrombin time and INR tests are nonspecific for vitamin K–dependent clotting factors and are often insensitive in patients with hepatic insufficiency because these patients may have an elevated PT/INR despite having normal concentrations of vitamin K.\textsuperscript{7,9,11,67} Despite the lack of literature proving its efficacy, vitamin K is commonly administered to patients with hepatic insufficiency to help correct their coagulopathy. Given the high safety profile and nominal cost of vitamin K, the risk-benefit profile of vitamin K will often favor its administration. There is no standardized dosing regimen; however, intravenous doses of 10 mg daily for 48–72 hours adequately replace vitamin K deficiency.\textsuperscript{2,28,67}

Replacing factor VII in hepatic insufficiency with rFVIIa is physiologically reasonable because these patients often have low levels of factor VII, and the small volume needed to administer rFVIIa may improve safety compared with FFP.\textsuperscript{28} Although several studies show that rFVIIa effectively normalizes prolonged values of PT/INR in patients with cirrhosis, the efficacy of rFVIIa for reducing clinically significant bleeding remains unclear. Bosch et al. conducted a double-blind study that randomized 245 patients with cirrhosis with upper GI bleeding to receive either eight doses of rFVIIa 100 mcg/kg or placebo, in addition to pharmacologic and endoscopic treatment.\textsuperscript{100} No significant differences were seen regarding the primary composite end
point (failure to control upper GI bleeding within 24 hours after the first dose, or failure to prevent rebleeding at 24 hours and day 5, or death within 5 days). However, subgroup analysis showed that administering rFVIIa in patients with Child-Pugh class B and C cirrhosis was more effective than placebo at improving the primary composite end point, whereas administration of rFVIIa in Child-Pugh A patients had no benefit. As a result of this subgroup analysis, the same investigators carried out a second randomized clinical trial that examined the same primary composite end point, but solely in patients with Child-Pugh class B and C cirrhosis. Results showed no significant differences between rFVIIa and placebo in these patients. As a result of these studies and the cost of rFVIIa, it is rarely administered to manage hemorrhage in patients with hepatic insufficiency.

The role of rFVIIa in the management of bleeding secondary to major surgical operations such as liver transplantation, resections, and/or liver biopsies also remains unclear. A multicenter, randomized, double-blind study examining the efficacy and safety of repeated perioperative doses of rFVIIa in liver transplantation secondary to cirrhosis failed to show any significant differences between placebo and rFVIIa with respect to perioperative PRBC transfusion requirements. Furthermore, there were no differences in requirements of FFP, platelets, and fibrinogen, and overall blood loss and length of hospital stay were similar. Other trials examining the use of rFVIIa in this patient population provide inconclusive evidence, and use has not been widely accepted during major surgical procedures secondary to hepatic insufficiency.

Finally, the prophylactic use of rFVIIa for invasive procedures in patients with acute liver failure is still highly debated. Limited data have shown that rFVIIa at a dose of 40 mcg/kg may be useful during invasive procedures, particularly the placement of intracranial pressure monitors. Compared with FFP alone, rFVIIa rapidly normalized PT/INR values, allowing for a higher number of successful intracranial pressure monitor placements. Despite the small amount of literature available, the role of rFVIIa as a prophylactic agent for invasive procedures remains uncertain, particularly because the normalization of
Coagulation tests in these patients has not been associated with clinically significant cessation of bleeding. Similar to rFVIIa, the role of PCCs for the management or prevention of bleeding associated with hepatic insufficiency is currently undefined, with much less data to support its use. Like rFVIIa, PCCs provide much smaller volumes of administration than FFP. Although data from large, randomized trials are lacking, several smaller studies have examined the safety and efficacy of PCC use in bleeding patients with hepatic insufficiency. In general, four-factor PCCs reverse prolonged PT/INR values in these patients, whereas three-factor PCCs require the addition of rFVIIa to be effective. Thromboelastography- or ROTEG-guided use of PCCs in bleeding associated with liver transplantation further reduces the need for RBCs, FFP, and platelets with no change in thromboembolic or ischemic events. Most data analyses currently available for the use of PCCs for bleeding associated with hepatic insufficiency were done using PT/INR as a surrogate marker of efficacy, yet these parameters do not predict bleeding risk in these patients. Prothrombin complex concentrates are often substituted for FFP to reverse PT/INR in patients with cirrhosis about to undergo invasive procedures because PCCs act more predictably and rapidly and require less volume administration. Further studies are ongoing and will help guide the clinical use of PCCs for bleeding associated with hepatic insufficiency. Continued caution is warranted when using PCCs because it is unknown whether a disruption of the coagulation system in these patients could place them at an increased risk of thrombosis.

**Major Obstetric Hemorrhage**

Pregnancy is associated with a hypercoagulable state because levels of factors V, VII, VIII, IX, X, and XII; vWF; and fibrinogen are increased with concomitant decreases in the anticoagulants protein C and S and heparin cofactor II and depressed antifibrinolytic activity. The transfusion rate in obstetrics in the United States is relatively low, from 0.9% to 2.3%. The incidence of postpartum
hemorrhage (PPH), however, is increasingly driven by the greater prevalence of uterine atony caused by higher rates of cesarian deliveries and the older average age of women at childbirth. Postpartum hemorrhage is defined as persistent bleeding of greater than 500–1,000 mL within 24 hours of birth that continues despite the use of initial measures.\textsuperscript{104,105} Fortunately, massive transfusion of 10 units or greater of blood products occurs in only 6 of every 10,000 deliveries. Although uterine atony represents about 80% of the causes of PPH, placental problems account for 27% of all cases of massive transfusion.\textsuperscript{104,105} Other etiologies of PPH include genital tract trauma and systemic medical disorders. Obstetrical DIC can occur secondary to placental abruption, amniotic fluid embolism, dead fetus syndrome, or massive hemorrhage.

First-line treatment of PPH consists of identifying and correcting the cause (e.g., removal of a retained placenta), using uterotonic agents (e.g., oxytocin, carboprost, or misoprostol) that improve uterine tone and cause local vasoconstriction to reduce blood flow to the uterus, and using mechanical manipulations (e.g., massage, uterine tamponade, packing).\textsuperscript{104,105} Persistent hemorrhage should mandate the activation of the MTP (\textsuperscript{12,38,40}Figure 24.3) with therapies directed to achieve or maintain the aforementioned laboratory goals for INR, platelet count, and fibrinogen concentrations (\textsuperscript{Table 24.6} and \textsuperscript{Table 24.8})\textsuperscript{2,3,7,35-40,56-66} or normal viscoelastic hemostatic parameters (\textsuperscript{Table 24.9; Figure 24.2})\textsuperscript{67,77,78} (see Traumatic Injury section for more detail). In some cases, topical hemostats may be applied. The results of a randomized, double-blind study of 144 women with PPH (greater than 800 mL of estimated blood loss after vaginal delivery) found that tranexamic acid (4 g loading dose, followed by 1 g/hour for 6 hours) significantly reduced blood loss, RBC transfusion requirement, bleeding duration, and progression to severe PPH.\textsuperscript{106} Although guidelines suggest the use of tranexamic acid in persistent PPH, a large, multicenter study is ongoing that will investigate the impact of tranexamic acid on the rates of hysterectomy and mortality. Recombinant activated factor VII may also cease or slow PPH, but it has only been assessed in retrospective cohort studies, most
commonly at doses of 90 mcg/kg.\textsuperscript{104,105} Recombinant activated factor VII may be a plausible option before the definitive treatment of a hysterectomy is performed.

**Managing Hemorrhage Associated with Anticoagulants**

About 1%–10% of patients receiving anticoagulation therapies will have a hemorrhagic complication.\textsuperscript{67} In all cases of hemorrhage, the benefit of reversing the anticoagulant in an effort to stop the bleed must be considered against the risk of thrombosis for which the anticoagulant is being used. In general, life-threatening bleeding events or those with long-term severe morbidities such as intracranial hemorrhage, retroperitoneal hemorrhage, GI hemorrhage, or intraocular hemorrhage mandate the temporary discontinuation and reversal of the anticoagulant. The extent of anticoagulation, if assessable, must be considered. In addition, the projected duration of effective anticoagulation after discontinuing the anticoagulant must be considered because reversal agents may have shorter half-lives than the anticoagulant, especially when organ dysfunction is present. For some bleeding sources, invasive or surgical procedures may be warranted.

Until recently, vitamin K antagonists such as warfarin were the only oral anticoagulants available for the prevention of thrombosis. In intracranial hemorrhage, the mortality rate doubles when it is associated with warfarin.\textsuperscript{1,2} Early hematoma expansion is associated with neurological deterioration and poor clinical outcomes.\textsuperscript{7,8} In severe or life-threatening intracranial hemorrhage, rapid reversal of anticoagulation is associated with clinical improvements, likely because hematoma expansion is minimized.\textsuperscript{9,10} Conventional therapies used to reverse the anticoagulant effects of warfarin include vitamin K, FFP, and PCCs (Table 24.5 and Table 24.6).\textsuperscript{2,3,7,35-38,56-66} Early administration of these agents is associated with greater reversal of INR, so these and other therapies should not be delayed for the results of coagulation tests.\textsuperscript{9,10} Intravenous vitamin K 5–10 mg should be administered in cases of major hemorrhage. Four-factor PCCs reduce
INR more rapidly than FFP and have become the primary reversal option for warfarin-associated hemorrhage. Recombinant activated factor VII is the most effective agent at reversing INR, but its use is controversial because it is costly and short acting relative to the duration of action of warfarin, and few studies have evaluated it for warfarin reversal. Studies evaluating rFVIIa for warfarin reversal are poor quality, and the results of studies of patients with spontaneous intracranial hemorrhage are mixed with respect to neurological improvement, although rFVIIa consistently reduces hematoma expansion at the risk of increasing thromboembolic events.

Target-specific oral anticoagulants include dabigatran (DTI) and the factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban). These newer agents have rapid onset of action and predictable pharmacokinetics, allowing for fixed dosing and mitigation of laboratory monitoring. Unlike warfarin, however, they do not currently have a known antidote. Several reversal agents are in development or at various stages of testing. The furthest along is idarucizumab, a monoclonal antibody that binds to free and thrombin-bound dabigatran and was recently shown to normalize clotting times in patients (79% at 24 hours) requiring urgent or emergency reversal of dabigatran. However, most data to treat hemorrhage associated with these agents are derived from animal models, in vitro studies of plasma from patients, or healthy volunteer studies that used outcomes of coagulation parameters or surrogate markers of clot formation such as thrombin generation (Table 24.2). Although dabigatran may be removed through dialysis, the factor Xa inhibitors cannot. Four-factor PCCs inconsistently reverse the effects of dabigatran, whereas they appear effective at promoting coagulation when anticoagulation is from factor Xa inhibitors. Both aPCCs and rFVIIa improve thrombin generation when anticoagulation is with dabigatran.

Other anticoagulants include heparin (stimulate anti-thrombin), low-molecular-weight heparins (stimulate antithrombin and anti-Xa activity), fondaparinux (indirect anti-Xa activity), other DTIs, and fibrinolytic agents (Table 24.2). The effects of heparin are reversed with protamine (1.0–1.5 mg protamine sulfate for every 100 U of heparin,
not to exceed 50 mg). Reversal of the anti-Xa activity of low-molecular-weight heparins can be 60% achieved with protamine, so FFP or PCCs are commonly administered as adjunctive therapy to replace additional factors. Anticoagulation associated with fondaparinux or the DTIs may partly be reversed by PCCs, aPCCs, or rFVIIa. Bleeding associated with fibrinolytic agents may be treated with antifibrinolytics and fibrinogen replacement with cryoprecipitate. Platelets and desmopressin are often administered to reverse the effects of antiplatelet agents (Table 24.2).\textsuperscript{7,11,12,30-33}

CONCLUSION

This chapter reviewed the common causes of disruption to the hemostatic pathways; delineated the properties of blood products, pharmacologic agents, and nonpharmacologic interventions; and discussed the appropriate management for common types of hemorrhage. Many questions remain regarding the pathophysiology of coagulopathy and hemorrhage and the appropriate use of procoagulant strategies.

LEARNING OBJECTIVES

1. Describe the most common laboratory methods for evaluating anticoagulation in critically ill patients.

2. Discuss the potential limitations of laboratory tests used to evaluate anticoagulation in critically ill patients.

3. Identify patient characteristics common to critically ill patients that should be considered when interpreting laboratory tests used for monitoring anticoagulation.

4. Compare and contrast different laboratory methods used to evaluate commonly prescribed anticoagulants.

ABBREVIATIONS IN THIS CHAPTER

ACT Activated clotting time
aPTT Activated partial thromboplastin time
DOAC Direct-acting oral anticoagulant
DTI Direct thrombin inhibitor
dTT Dilute thrombin time or plasma diluted thrombin time
ICU Intensive care unit
INTRODUCTION

Coagulation tests are often used within critical care medicine. Accurate measurement of the coagulation status can be crucial for the correct treatment of an intensive care unit (ICU) patient. Coagulation tests may be used to evaluate patients for coagulation abnormalities or comorbidities, for diagnostic purposes, or to monitor antithrombotic medications. Many variables, including critical illness, must be considered when interpreting coagulation tests in the ICU because they may affect the accuracy of test results. This chapter will review most of the coagulation tests available for critical care clinicians. When interpreting information provided within this chapter, it is important to understand that different instruments and testing approaches are used depending on the health care institution. Therefore, tests may be used differently, and variability in reported values should be expected when comparing information provided within this chapter, data from available clinical studies, and laboratory results in your clinical setting. Of note, laboratory tests used for monitoring anticoagulants are by definition a surrogate marker for anticoagulation outcomes. In many situations, laboratory tests and therapeutic ranges have been developed according to in vitro mechanisms and have not been formally evaluated in clinical trials to determine their correlation with definitive outcomes.
such as thromboembolism or bleeding. It is critical that interpretation of the results from the coagulation tests used be confirmed with the clinical scenario observed at the bedside.

**METHODS OF COAGULATION TESTING**

Coagulation testing can be conducted by different methodologies, with most tests being either functional or antigenic (Box 25.1). Clot-based assays typically use citrated platelet-poor plasma. The testing is performed with the use of re-agents at normal body temperature (37°C). Some tests (e.g., activated partial thromboplastin time [aPTT]) require a short incubation period to allow activator and phospholipids to interact with plasma factors. The clotting end point is determined by changes in light scattering because of turbidity induced by fibrin formation. Chromogenic versions of assays use a color formed after the addition of reagent to determine the anticoagulant activity present (Figure 25.1). Antibody-related assays incorporate an antigen/antibody complex to measure a specific antigen or antibody present within the patient sample. Some assays must be performed by a laboratory, whereas others can be conducted at or near the bedside (commonly called point-of-care testing). Point-of-care testing, which has increased in availability and popularity, is often used in operating rooms and in some critical care specialty units. As a rule, point-of-care testing results should be evaluated in comparison with central laboratory results. Bias in results should be expected, especially at the low and high ends of the testing range for many tests.

**Box 25.1. Coagulation Test Methodology**

**Functional tests:**
Clotting end point – Adding patient plasma to reagent(s) and then determining the amount of clot formation. Examples: PT (prothrombin time), aPTT (activated partial thromboplastin time), ACT (activated clotting time), TT (thrombin time), fibrinogen, factor
activity

Chromogenic testing – Adding patient plasma to reagent(s) and then determining the amount of color formation. Examples: Factor activity, anti-Xa, antithrombin activity

Aggregation – Adding patient plasma (platelet poor or containing platelets) to platelets and/or agonist(s) and measuring light scattering (agglutination) or platelet clumping (aggregation). Examples: Heparin-induced thrombocytopenia, platelet function

Antigenic tests:
Immunologic – Adding patient plasma or serum to beads or microwells containing target antigen or antibody and then assessing color changes, changes in agglutination, hemagglutination, etc. Examples: Fibrinogen, factor activity, Ddimer, heparin-induced thrombocytopenia, antithrombin

Most screening coagulation assays (e.g., prothrombin time [PT] or aPTT) are based on how rapidly fibrin clots form in patient samples. The type of activator used will trigger different coagulation pathways. For example, thromboplastin is used to trigger the extrinsic pathway, kaolin is used to trigger the intrinsic pathway, and viper venoms are used to trigger the common pathway. There are different methods of detecting the formation of fibrin in these assays, including visual, mechanical, photo-optical, and viscoelastographic techniques (Figure 25.2).

REGULATORY REQUIREMENTS FOR CLINICAL USE OF LABORATORY TESTS

Clinical Laboratory Improvement Amendments (CLIA) regulations govern the use of laboratory tests in patients. The U.S. Food and Drug Administration (FDA)-approved commercially available tests must comply with these regulations. However, in many coagulation tests,
institutions must individually determine the accuracy, precision, and reportable ranges. Any modifications to an FDA-approved test, the use of a “for research purposes only test,” or the use of a homegrown test requires that the laboratory evaluate the performance of the assay according to the CLIA regulations, with additional testing for sensitivity and specificity.

**OBTAINING A RELIABLE SAMPLE FOR TESTING**

Acquiring and appropriately delivering a patient sample to the laboratory for analysis is a critical step in evaluating anticoagulant intensity. The sample should be free of tissue and intravenous solutions delivered through indwelling lines. Obtaining a proper sample is most problematic in patients with a central venous catheter, particularly those being used for extracorporeal circuits or that have large volumes of medication infusions running through them. If syringes are used for collecting the sample, immediate (within 1 minute) transfer to the collection tube will minimize alterations in coagulation test results. Adequate techniques should be used to avoid dilution of the sample or contamination with infusing medications during the collection process. Samples should not be placed on ice because this can affect factor and platelet function. Withdrawal and waste of 5–10 mL of volume may be necessary before a proper blood draw can be obtained. Once the sample is obtained, it should be sent to the laboratory quickly and preferably tested within 2 hours. Prolonged incubation at room temperature for greater than 24 hours can result in significantly altered activity of clotting factors. The appropriateness of a blood draw should be considered any time a result is discordant with what is being observed clinically in a patient. If the test is believed to be misrepresenting the clinical scenario, repeating a test may be necessary before making clinical decisions.
Figure 25.1 Chromogenic anti-Xa test.

Figure 25.1 depicts how the chromogenic anti-Xa assay is performed. Blood activates the patient’s antithrombin III, and they both act to deactivate the factor X. As heparin level in the blood increases, more factor X is deactivated, and the less active Xa is left in the test tube. Factor II (marked with a yellow marker) is added into the test tube. The active Xa remaining interacts with the factor II, and the yellow marker is released. This is then measured. The amount of heparin is deduced from the amount of color change.

BASELINE LABORATORY STUDIES FOR PATIENTS INITIATED ON ANTICOAGULATION

All critically ill patients should have certain laboratory tests measured before initiation of anticoagulation therapy. At a minimum, a baseline complete blood cell count to evaluate platelets, hemoglobin, and hematocrit and an assessment of renal function and hepatic function tests should be considered. Platelet monitoring should continue during therapy for patients taking heparin products (see Chapter 23, “Prevention and Treatment of Venous Thromboembolism”). Laboratory tests to evaluate for thrombophilias such as lupus anticoagulant (e.g.,
dilute Russell viper venom time and lupus-sensitive PTT) should be considered in patients with an unexplained thrombosis in a vein or artery, recurrent miscarriages, or an unexplained prolonged PTT test.

For many anticoagulant tests, it is important to determine whether the patient’s baseline values are within normal limits so that clinicians can determine whether alterations in the target therapeutic range or additional testing is needed. These include the PT/international normalized ratio (INR) (if initiating Coumadin) and the aPTT (if initiating UFH or a direct thrombin inhibitor [DTI]). The patient’s weight and creatinine clearance should be measured for any weight-based medications that are renally eliminated. The decision to monitor these laboratory values and the frequency of monitoring throughout anticoagulation therapy should be considered depending on the anticoagulant chosen, laboratory test, and clinical situation. Physical examination findings, ultrasonography, Doppler, computed tomography, or other imaging studies may be useful for evaluating the presence or extension of thromboembolism and should be evaluated as appropriate in addition to coagulation tests to assist with anticoagulant choice, dosing, and monitoring strategies.

---

**ALTERATIONS IN COAGULATION TESTING**

When interpreting the results of a coagulation test, it is critically important to determine whether the test is providing an accurate assessment of the patient’s coagulation status. To do this, everything from the time of the blood draw until the result is reported from the laboratory must be evaluated. Most blood samples collected for coagulation testing will be placed in a tube containing citrate, which inhibits coagulation by binding to calcium. As mentioned previously, it is preferred to use systems that allow for direct transfer from a vascular device to the collection tube. In addition to alterations in results because of improper acquisition or handling of the sample, patient factors or conditions can affect laboratory tests. Common conditions affecting PT and aPTT are listed in Table 25.1. In certain situations listed in Table 25.1, the CLSI (Clinical & Laboratory Standards
Institute) guidelines require special processing of specimens. For example, in specimens from patients with polycythemia or hematocrit values greater than 55%, a spurious prolongation of coagulation studies may occur because of a relative excess of citrate anticoagulant in relation to plasma volume. If the citrate concentration is not adjusted in this situation, citrate may bind to calcium added to initiate the clotting process and slow its initiation, leading to prolonged PT and aPTT.\(^5\)

![Figure 25.2 Methods of clot detection.](image)

Mechanical: There are different mechanical methods, but these are either based on the movement of a metal ball between two magnets or based on the movement of two probes inserted within the patient sample. Fibrin formation restricts movement of the magnetic
ball or movement of the probe in relation to each other, resulting in a finite end point, which is recorded as the clotting time.

Photo-optical: With this technique, fibrin formation is detected by the change in optical density or turbidity of the sample. The results are usually recorded as the time to clot; however, some analyzers also provide a curve of clot formation.

Viscoelastic: With this technique, a probe is inserted into a cup containing the patient sample. Then, either the probe is rotated within the cup or the cup is rotated around a fixed probe. Changes in the movement of the cup in relation to the probe result in a tracing that reflects the kinetics of fibrin formation and fibrinolysis, with numerical measurements pertaining to these kinetics and the strength of the resulting fibrin clot.

The complex interplay of patient, sample, and laboratory environment factors makes communication with the laboratory an important part of patient care. Alerting laboratory staff to the anticoagulant being monitored and the condition of the patient may provide them with enough information to allow for sample alteration (e.g., dilution of sample), additional testing, or correction of values. They can also provide clinicians with specific information regarding the reagents being used and their sensitivity to outside influences commonly occurring in critically ill patients.

**PT AND INR**

The PT is a measure of the extrinsic and final common pathway of clotting. This consists of tissue factor, fibrinogen (I), and coagulation factors II, V, VII, and X (Figure 25.3). In hospitalized patients, the PT is done on a venipuncture-acquired sample and analyzed using a laboratory-based coagulation analyzer. In the test, clotting is initiated by recalcifying citrated patient plasma in the presence of thromboplastin. The PT measures the time it takes plasma to form a fibrin clot after the addition of calcium and thromboplastin. The clot can be detected by visual, optical, or electromechanical means. The PT result is expressed in seconds. Variations in PT occur because of the source of thromboplastin and the type of instrument used for clot detection. Therefore, thromboplastin reagent sensitivity is expressed using the term international sensitivity index (ISI). The INR was created as a mechanism to adjust for variation in PTs because of
thromboplastin reagent sensitivity.

The equation for the INR is as follows:

\[
\text{INR} = \left[\frac{\text{patient PT}}{\text{laboratory’s geometric mean for normal patients}}\right]^{\text{SI}}
\]

The PT/INR is sensitive to the vitamin K–dependent clotting factors (e.g., factors II, VII, and X); therefore, it is commonly used to evaluate the anticoagulant effects of vitamin K antagonists. Of note, the INR describes only the activity of factors II, VII, and X, and not factor IX or protein C and S. Most PT reagents also contain heparin-binding chemicals to block the effect of unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and fondaparinux. However, at high heparin levels, the heparin binders may become saturated, and the PT may be prolonged.

aPTT = activated partial thromboplastin time; PRBC = packed red blood cell; PT = prothrombin time.

For most patients taking warfarin, the goal steady-state INR for most indications is 2–3. The full anticoagulant effect of warfarin is delayed until the normal clotting factors are eliminated from the circulation. The INR is less accurate during the initial few days of warfarin therapy because the INR is most reflective of reductions in factor VII, which has a much shorter half-life than factor II. This may lead a clinician to assume that a greater degree of anticoagulation is present in the patient than actually exists. In contrast, as warfarin is held or removed, an increase in factor VII activity may have a reduction in INR that underestimates the degree of anticoagulation present. Inaccuracies can also occur because of errors in ISI reporting or use and differences in laboratory instrumentation. Comorbidities such as hepatic disease and the presence of lupus anticoagulant can prolong the INR. The use of anticoagulants such as DTIs can prolong the PT/INR in a dose-dependent fashion. The DTIs interact with the coagulation test, and of note, a prolonged PT/INR is not indicative of their anticoagulant effect. The elevation in INR can be significant, particularly with the parenteral anticoagulants, with argatroban causing greater increases than bivalirudin, lepirudin, and desirudin. The effects
of dabigatran on the INR are less pronounced.

---

**CHROMOGENIC FACTOR X ACTIVITY**

The chromogenic factor X assay is an alternative to the INR for monitoring patients taking warfarin. The chromogenic factor X assay is a phospholipid-independent test, which prevents it from being altered by coagulation abnormalities such as lupus anticoagulant. In this case, the chromogenic factor X activity can be measured at the same interval as the INR would typically be completed. Chromogenic factor X results are reported as a percentage of normal activity and are inversely related to INR values. A chromogenic factor X level of 20%–25% approximates an INR of 3, and a level of 40%–45% approximates an INR of 2. The main drawbacks of the test include its expense and availability. Results may take 24–72 hours depending on the availability of the laboratory within the institution.

In addition to using it in patients with altered INR values at baseline, the chromogenic factor X activity assay may be useful for monitoring warfarin in critically ill patients who are taking DTIs and transitioning to warfarin therapy. Interpretation of the INR can be difficult in these patients because DTIs inhibit thrombin and prevent fibrin clot formation. This results in a falsely elevated PT and INR in a concentration-dependent manner. Because DTIs do not affect factor X, a potential option to evaluate the effects of warfarin without having to hold DTI therapy is to use the chromogenic factor X assay. The chromogenic factor X assay is capable of evaluating the effects of warfarin while excluding the anticoagulant effects of DTIs. Similar to patients on warfarin monotherapy, a chromogenic factor X level of less than 45% predicts an INR of 2 or greater with around 80% specificity and 60%–90% sensitivity. Once this level is achieved, a therapeutic INR for warfarin should be verified by discontinuing the DTI and measuring a PT/INR after the DTI has been appropriately cleared (typically 4 hours or more after discontinuing the DTI) from the systemic circulation. Although this approach is likely to be reasonable for most critically ill patients, the reliability of the chromogenic factor X assay is diminished.
in patients with hepatic dysfunction or vitamin K deficiency.

**ACTIVATED PARTIAL THROMBOPLASTIN TIME**

The aPTT is a global assay of coagulation. The aPTT can be used to screen for inhibitors and deficiencies of the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, factors XII, XI, IX, and VIII) and the final common pathway (factors II, X, V, prothrombin) and fibrinogen (Figure 25.3). The aPTT is performed by recalcifying citrated plasma in the presence of a thromboplastic material that does not have tissue factor activity and a negatively charged substance (e.g., kaolin), which results in contact factor activation, thereby initiating coagulation by the intrinsic pathway. Several variables can affect the aPTT including sample timing, site of sample, citrate concentration, and sample handling and processing time (Table 25.1). The reagents used for the aPTT vary in type of contact activator, phospholipid composition, and concentration. Deficiency in all clotting factors except factor VII can cause prolongation of the aPTT. The relationship between the factor activity in the blood and the aPTT result is logarithmic. For elevated baseline aPTTs, a lower level of change is needed for additional prolongation.
